Abstract

This paper proposes a physical-statistical modeling approach for spatio-temporal data arising from a class of stochastic convection-diffusion processes. Such processes are widely found in scientific and engineering applications where fundamental physics imposes critical constraints on how data can be modeled and how models should be interpreted. The idea of spectrum decomposition is employed to approximate a physical spatio-temporal process by the linear combination of spatial basis functions and a multivariate random process of spectral coefficients. Unlike existing approaches assuming spatially- and temporally-invariant convection-diffusion, this paper considers a more general scenario with spatially-varying convection-diffusion and nonzero-mean sourcesink. As a result, the temporal dynamics of spectral coefficients is coupled with each other, which can be interpreted as the non-linear energy redistribution across multiple scales from the perspective of physics. Because of the spatially-varying convectiondiffusion, the space-time covariance is non-stationary in space. The theoretical results are integrated into a hierarchical dynamical spatio-temporal model. The connection is established between the proposed model and the existing models based on Integro-Difference Equations. Computational efficiency and scalability are also investigated to make the proposed approach practical. The advantages of the proposed methodology are demonstrated by numerical examples, a case study, and comprehensive comparison studies. Computer code is available on GitHub.

Key words: Convection-diffusion processes, spatio-temporal modeling, hierarchical dynamical spatio-temporal models, spectral method, radar-based precipitation nowcasting

1 Introduction

Digitization of the physical space has led to an explosive growth of spatio-temporal data from physical convection-diffusion processes. Examples span multi-disciplinary areas including environmental science, meteorology, remote sensing, geology, engineering, etc. For such processes, fundamental physics imposes critical constraints on how data can be modeled and how models should be interpreted. This paper proposes a statistical modeling approach for spatio-temporal data arising from a generic class of convection-diffusion processes described by a Stochastic Partial Differential Equation (SPDE). By considering spatiallyvarying convection-diffusion, the proposed modeling approach makes critical extensions to the recent advances on the PDE-based statistical modeling of spatio-temporal data.

1.1 Motivation and Background

Convection-diffusion equations have been widely used to describe how physical quantities (e.g., particles, air pollutant, energy, rain cells, heat, etc.) are transferred inside a physical system due to two processes: convection and diffusion. Interdisciplinary examples include, but are not limited to, urban air pollution processes, remote sensing of extreme weather systems such as hurricanes, decomposition of polymer in space and time, propagation of smoke from wildfires, regional epidemics of infectious diseases, etc. (Stroud et al., 2010; Guinness and Stein, 2013; Sigrist et al., 2015; Liu et al., 2016; Zhuk et al., 2017; Liu et al., 2018; Guan et al., 2020).

For spatio-temporal data arising from physical convection-diffusion processes, deterministic physics-based numerical models are less effective for real-time operations due to the high computational cost and the ineffectiveness in utilizing real-time sensor data streams—a major source of information in the era of Big Data. For many complex physical processes, it is not only challenging to build the physics models from the first principles but also difficult to handle the high-degree uncertainty associated with model parameters and model inputs.

Statistical spatio-temporal models, on the other hand, have been proven useful for shortterm prediction and space-time interpolation using observations (Wikle et al., 2001; Guinness and Stein, 2013; Liu et al., 2016; Kuusela and Stein, 2017; Reich et al., 2018; Guan et al., 2020). For spatio-temporal data arising from physical processes, however, governing physics imposes critical constraints on how data can be modeled and interpreted. For example, the space-time covariance structures, to a great extent, are determined by the convection-diffusion equations from which the data are generated. When the critical connection to fundamental physics is missing, the capabilities of pure data-driven approaches may not be fully appreciated by domain experts for monitoring, prediction and planning purposes. In addition, for non-stationary and highly dynamic processes, the specification of statistically-adequate and physically-meaningful space-time covariance structures is known to be extremely challenging (Nychka and Wikle, 2002; Cressie and Wikle, 2011; Simpson et al., 2012). Assumptions, such as isotropic, stationary and space-time separable, have been widely adopted which make the models mathematically tractable but too simple (or too abstract) to acknowledge the full complexity of the underlying physical processes. Hence, there is an urgent demand for intepretable models and computationally efficient algorithms tailored for large-scale spatio-temporal data arising from physical processes. When operational insights are required based on domain knowledge, our engagement with industry indicates that pure data-driven approaches could be limited even in data-rich scientific and engineering environments. As the volume of data increases, this issue appears to be more crucial than ever when statistical models are inevitably becoming more complex but seemingly less interpretable. Hence, data intensive physical analytics–an emerging field which resides at the intersection of physical modeling and statistics (Hamann, 2016; Qian et al., 2019)–is being actively pursued in both academia and industry.

1.2 Literature Review

The pioneering work of statistical modeling of spatio-temporal data can be found in Banerjee et al. (2004), Schabenberger and Gotway (2005) and Cressie and Wikle (2011). The mainstay approach models spatio-temporal processes by random fields with fully specified space-time covariance. This approach is referred to as the geostatistical paradigm and has gained tremendous popularity and success over the past decades. However, the specification of space-time covariance structures is known to be challenging for non-stationary and highly dynamic processes. Consider, for example, the modeling of urban air quality data collected by monitoring stations (Liu et al., 2016). The space-time correlation of the pollutant dispersion process depends on wind, temperature, solar radiation and traffic, and is too complex to be directly specified and validated. Similar examples can be found in the modeling of dynamic weather systems where the space-time covariance is non-stationary and depends on highly dynamic factors such as wind, small-scale localized convection, etc. (Liu et al., 2018). Hence, there have been prolonged research interests to provide flexible and effective ways to construct non-stationary covariance functions (Cressie and Huang, 1999; Gneiting, 2002; Fuentes et al., 2005; Gneiting et al., 2006; Ghosh et al., 2010; Reich et al., 2011; Lenzi et al., 2019). Moreover, the geostatistical modeling paradigm can be computationally expensive for large spatio-temporal data sets due to the prohibitive cubic operations $\mathcal{O}((TN)^3)$, where T and N are the number of samples in time and space (Cressie and Wikle, 2011; Banerjee and Fuentes, 2012; Simpson et al., 2012; Yan et al., 2018). For example, a standard dual polarization meteorological Doppler weather radar image contains 230,400 pixels and new images are generated every 5 minutes. Due to the high computational cost, approximations are commonly used for large problems; for example, Gaussian Markov Random Fields representation (Lindgren and Rue, 2011), Nearest-Neighbor Gaussian Process (Datta et al., 2016; Banerjee, 2017), kernel convolution (Higdon, 1998), low rank representation (Cressie and Johannesson, 2002; Nychka and Wikle, 2002; Banerjee et al., 2008), approximation of likelihood functions (Stein et al., 2004; Fuentes, 2007; Guinness and Fuentes, 2015), Bayesian inference for latent Gaussian models based on the integrated nested Laplace approximations (Rue et al., 2009; R-INLA, 2019), Lagrangian spatio-temporal covariance function (Gneiting et al., 2006), matrix-free state-space model (Mondal and Wang, 2019), Vecchia approximations of Gaussian processes (Katzfuss et al., 2020), as well as the multi-resolution approximation (M-RA) of Gaussian processes observed at irregular spatial locations (Katzfuss, 2017).

A powerful modeling framework, known as the Hierarchical Dynamical Spatio-Temporal Models (DSTM), has been proposed (Wikle and Cressie, 1999; Berliner, 2003; Cressie and Wikle, 2011; Stroud et al., 2010; Katzfuss et al., 2020). The power of the DSTM comes from the dynamical model specification by a series of conditional models that lead to a complex joint space-time covariance structures which can hardly be directly specified. Stroud et al. (2001) investigated a Gaussian state space framework where the mean function at each time is modeled by a locally weighted mixture of linear regressions. The use of Monte Carlo approaches makes the dynamical model more computable with very large data sets and for non-linear non-Gaussian models (Carlin et al., 1992; Banerjee et al., 2004).

The SPDE-based modeling approach of large spatio-temporal data has also drawn much attention due to its connection to many physical convection-diffusion processes. Jones and Zhang (1997) developed statistical models for unequally spaced data arising from continuous stationary space-time processes described by a SPDE with white noise. Spectral density functions were obtained for the stationary space-time process and the inverse Fourier transform was employed to obtain the covariance functions. Brown et al. (2000) proposed a blur-generated non-separable space-time models and showed the explicit link of the proposed model to a convection-diffusion SPDE in the limiting case. Hooten and Wikle (2008) proposed a hierarchical Bayesian model for the spread of invasive species with spatiallyvarying diffusion coefficients as well as a logistic population growth term based on a common reaction-diffusion equation. Stroud et al. (2010) proposed a methodology for combining spatio-temporal satellite images with advection-diffusion models for interpolation and prediction of environmental processes. Lindgren and Rue (2011) investigated the explicit connection between a convection-diffusion SPDE and Gaussian Markov random field. Signist et al. (2015) proposed a systematic approach to obtain a Gaussian process by solving a SPDE with a convection-diffusion operator that does not vary in space and time. In the literature of computational mechanics, Qian et al. (2019) proposed a physics-informed method for learning low-dimensional models for large-scale dynamical systems govern by PDE. It is noted that a DSTM can also be motivated by special types of partial differential equations (e.g., diffusion, reaction-diffusion, or simplified convection-diffusion equations) under special conditions (e.g., spatially- and temporally-invariant convection-diffusion). A summary of the latest advances in the spatial modeling with SPDE can be found in Cressie and Wikle (2011) and Krainski et al. (2019).

1.3 Overview of the Paper

This paper proposes a statistical modeling approach for spatio-temporal data arising from a generic class of convection-diffusion SPDE with a spatially-varying convection-diffusion operator and a nonzero-mean spatio-temporal source-sink term. We employ the important idea of spectrum decomposition to approximate the spatio-temporal process governed by a SPDE. Unlike the existing results based on spatially- and temporally-invariant convection-diffusion, the proposed model has two critical differences: (i) the temporal dynamics of spectrum coefficients is coupled when the convection-diffusion operator varies in space. Such a phenomenon is interpreted as the non-linear energy transfer or redistribution across multiple scales from the perspective of physics; (ii) while spatially- and temporally-invariant convection-diffusion leads to a stationary process in the limiting case, the proposed spatio-temporal model has a non-stationary space-time covariance structure due to the spatially-varying convectiondiffusion. To our best knowledge, such a statistical modeling methodology is not yet available in the literature.

In Section 2, we describe the general modeling framework and present the key theoretical results. Section 3 focuses on real-valued processes under discrete sampling—a typical scenario in scientific and engineering applications. In Section 4, a systematic approach is presented to integrate the established theoretical results into the DSTM framework. Section 5 provides a numerical example, and a case study of radar-based precipitation nowcasting to demonstrate the advantages of the proposed method.

2 The General Modeling Framework

Consider a spatio-temporal convection-diffusion process governed by the following SPDE:

$$\mathcal{A}\xi(t, \boldsymbol{s}) = Q(t, \boldsymbol{s}) + \varepsilon(t, \boldsymbol{s}) \tag{1}$$

where $\xi(t, \mathbf{s})$ is a spatio-temporal process in space \mathbf{s} and time t, $Q(t, \mathbf{s})$ is the source-sink term, $\varepsilon(t, \mathbf{s})$ is a spatio-temporal error process, and \mathcal{A} is the convection-diffusion operator:

$$\mathcal{A}\xi(t,\boldsymbol{s}) = \frac{\partial}{\partial t}\xi(t,\boldsymbol{s}) + \boldsymbol{\vec{v}}_{t,\boldsymbol{s}}^T \nabla \xi(t,\boldsymbol{s}) - \nabla \cdot [\boldsymbol{D}_{t,\boldsymbol{s}} \nabla \xi(t,\boldsymbol{s})] + \zeta_{t,\boldsymbol{s}}\xi(t,\boldsymbol{s})$$
(2)

where $\vec{v}_{t,s}$, $D_{t,s}$, $\zeta_{t,s}$, ∇ and ∇ represent the velocity, diffusivity, decay, gradient and divergence, respectively.

The SPDE (1) describes the transport of particles, energy, or other physical quantities by convection and diffusion processes. The second term on the right hand side of (2) models the convection of a physical quantify by an ambient flow, while the third and the last terms represent diffusion and decay, respectively. Depending on the applications, (1) is referred to as the convection-diffusion, advection-diffusion, drift-diffusion, or scalar transport equations. When applied to model real data, the SPDE (1) is not exactly satisfied due to the uncertainties in the model parameters. For example, the measurement errors or noises introduce aleatoric uncertainties in the velocity $\vec{v}_{t,s}$ and diffusivity $D_{t,s}$ (see Proposition 1), while our incomplete knowledge on the forcing term, Q(t, s), often leads to epistemic uncertainties (see the case study in Section 5). Hence, by incorporating the error process $\varepsilon(t, s)$ into the SPDE (1), one can exploit the capability of statistical approaches to quantify the sources of uncertainty for complex physical processes.

The spectral decomposition of $\xi(t, \mathbf{s})$ is given by the linear combination of spatial basis functions and random spectral coefficients (Wikle and Cressie, 1999; Cressie and Wikle, 2011; Sigrist et al., 2015; Mak et al., 2018; Qian et al., 2019):

$$\xi(t, \boldsymbol{s}) \approx \tilde{\xi}(t, \boldsymbol{s}) = \sum_{j=1}^{K} \alpha_j(t) f_j(\boldsymbol{s}) \equiv \boldsymbol{f}^T(\boldsymbol{s}) \boldsymbol{\alpha}(t).$$
(3)

Here, $\boldsymbol{\alpha}(t) = (\alpha_1(t), ..., \alpha_K(t))^T$ is a multivariate temporal process of spectral coefficients, $f_j(\boldsymbol{s}) = \exp(i\boldsymbol{k}_j^T\boldsymbol{s})$ is the deterministic Fourier basis function, \boldsymbol{k}_j is the spatial wavenumber, and $\boldsymbol{f}(\boldsymbol{s}) = (f_1(\boldsymbol{s}), ..., f_K(\boldsymbol{s}))^T$. The choice of Fourier spatial basis function is appropriate if $\xi(t, \boldsymbol{s})$ is periodic. The spectral decomposition (3) provides some key advantages in modeling the spatio-temporal data arising from the physical process (1):

- Once the spatial basis functions have been fixed, the modeling of a spatio-temporal process $\xi(t, s)$ can be converted to the modeling of a multivariate stochastic process $\alpha(t)$. The latter problem is often more tractable.
- If it is possible to find a multivariate stochastic process $\alpha(t)$ such that the approximated process generated by (3) also satisfies the SPDE (1), the fundamental physics in (1) can be naturally built into the statistical model (Wikle and Cressie, 1999; Sigrist et al., 2015; Qian et al., 2019). Alternatively, one may choose to model $\alpha(t)$ by pure data-driven approaches, if incorporating physics into statistical models is not a major modeling concern (Yeo and Melnyk, 2018).
- Once the temporal dynamics of $\boldsymbol{\alpha}(t)$ has been established, the space-time covariance structure of $\tilde{\xi}(t, \boldsymbol{s})$ can be derived from the spectral decomposition (3), where $\tilde{\xi}(t, \boldsymbol{s})$ is a linear combination of $\boldsymbol{\alpha}(t)$ and known basis functions $\boldsymbol{f}(\boldsymbol{s})$.
- Dimension reduction is possible by retaining only the low-frequency components in (3), which helps to achieve a tremendous computational advantage without significantly sacrificing the modeling accuracy. This is often a critical step that ensures the proposed model to be practical for certain applications as shown in the case study.
- The model based on (3) can be integrated into the framework of DSTM (Wikle et al., 1998; Berliner, 2003; Cressie and Wikle, 2011), which enables computationally efficient algorithms for statistical inference, monitoring and prediction.

We firstly show, in Proposition 1, that a multivariate stochastic process $\boldsymbol{\alpha}(t)$ does exist such that the approximated process generated by (3) satisfies the SPDE (1). The following assumptions are made: (A1) the convection-diffusion operator \mathcal{A} in (2) is spatiallyvarying but temporally-invariant (i.e., $\vec{v}_{t,s} = \vec{v}_s$, $D_{t,s} = D_s$, $\zeta_{t,s} = \zeta_s$); (A2) the sourcesink process Q(t, s) admits a spectral representation $Q(t, s) = f^T(s)\beta(t)$ with $\beta(t) =$ $(\beta^{(1)}(t), ..., \beta^{(K)}(t))^T$ dynamically evolving over time; (A3) the error process $\varepsilon(t, s) = f^T(s)\tilde{\varepsilon}(t)$ is a white-in-time stationary spatial process where $\tilde{\varepsilon}(t)$ is a K-dimensional random vector; (A4) the initial condition is given by $\tilde{\xi}(0, s) = f^T(s)\alpha(0)$ where $\alpha(0) \sim N(0, \text{diag}\{\tilde{h}_0(k_j)\})$ and $\tilde{h}_0(k_j)$ is the spectral density. Proposition 1. For spatially-varying convection-diffusion (i.e., A1), if the initial condition $\tilde{\xi}(0, \mathbf{s})$, source-sink process $Q(t, \mathbf{s})$ and error process $\varepsilon(t, \mathbf{s})$ are in a space \mathbb{S} spanned by a finite number of Fourier functions $\mathbf{f}^T(\mathbf{s})$ (i.e., A2~A4), then, there exists a multivariate temporal process $\alpha(t)$ such that $\tilde{\xi}(t, \mathbf{s})$ remains in \mathbb{S} and satisfies the SPDE (1). The process $\alpha(t)$ is characterized by a stochastic Ordinary Differential Equation (ODE) as follows:

$$\dot{\boldsymbol{\alpha}}(t) = \boldsymbol{G}\boldsymbol{\alpha}(t) + \boldsymbol{\beta}(t) + \tilde{\boldsymbol{\varepsilon}}(t).$$
(4)

Here, the (i, j)th entry of the non-diagonal matrix G is given by

$$g_{i,j} = C_j^{-1} \int_{\mathbb{S}} \left\{ -\boldsymbol{k}_j^T \boldsymbol{D}_{\boldsymbol{s}} \boldsymbol{k}_j - \zeta_{\boldsymbol{s}} - \imath (\boldsymbol{\vec{v}}_{\boldsymbol{s}}^T \boldsymbol{k}_j - [\nabla \cdot \boldsymbol{D}_{\boldsymbol{s}}]^T \boldsymbol{k}_j) \right\} f_j(\boldsymbol{s}) f_i^*(\boldsymbol{s}) d\boldsymbol{s}$$
(5)

where i is the imaginary unit, $C_j = \int f_j(\mathbf{s}) f_j^*(\mathbf{s}) d\mathbf{s}$, \cdot^* represents the complex conjugation, and the covariance of the error process $\tilde{\boldsymbol{\varepsilon}}(t)$ is given by $\operatorname{cov}(\tilde{\boldsymbol{\varepsilon}}(t), \tilde{\boldsymbol{\varepsilon}}(t')) = \delta_{t,t'} \operatorname{diag}{\{\tilde{h}(\boldsymbol{k}_j)\}}$ with $\delta_{t,t'}$ and $\tilde{h}(\cdot)$ respectively being the Kronecker delta and spectral density function.

Remark. The proof of Proposition 1, using the Galerkin method, is provided in Appendix A. The temporal evolution of $\alpha(t)$ described by the ODE (4) has interesting interpretations: the first term on the right hand side, $G\alpha(t)$, captures the transition of the spectral coefficients $\alpha(t)$ due to the convection-diffusion operator \mathcal{A} ; the second term, $\beta(t)$, captures the additional change to $\alpha(t)$ due to the source-sink Q(t, s); and the third term $\tilde{\varepsilon}(t)$ captures the uncertainty associated with the evolution of $\alpha(t)$ due to the error process $\varepsilon(t, s)$ in (1).

Note that the process $\boldsymbol{\alpha}(t)$ defined in (4) differs from the existing result in the literature. Since \boldsymbol{G} is non-diagonal given a spatially-varying convection-diffusion operator \mathcal{A} , the ODE (4) immediately implies that the temporal evolution of the components in $\boldsymbol{\alpha}(t)$ are coupled: at any time t, the transition of each component in $\boldsymbol{\alpha}(t)$ depends not only on itself, but also on all other components in $\boldsymbol{\alpha}(t)$. If the Fourier coefficients are viewed as the energy distributed to different frequencies, the coupling of Fourier coefficients can be naturally interpreted as the energy transfer across multiple scales, i.e., the spatially-varying convectiondiffusion redistributes the energy across different frequencies. Under a special case when the convection-diffusion operator does not vary in space and time, and the source-sink is negligible (i.e., $Q(t, \boldsymbol{s}) = 0$, $\vec{v}_{t,s} = \vec{v}$ and $\boldsymbol{D}_{t,s} = \boldsymbol{D}$), the ODE (4) degenerates to the result in Sigrist et al. (2015) where the temporal evolution of the components in $\boldsymbol{\alpha}(t)$ are completely de-coupled (i.e., \boldsymbol{G} becomes diagonal), leading to a stationary solution of (1) in the limiting case; also see Brown et al. (2000). When the velocity field \vec{v}_s and diffusivity \boldsymbol{D}_s vary in space, however, the process considered in our model becomes non-stationary in space.

Once the temporal dynamics of $\boldsymbol{\alpha}(t)$ has been established, the space-time covariance of $\tilde{\xi}(t, \boldsymbol{s})$ is derived from the spectral decomposition (3), where $\tilde{\xi}(t, \boldsymbol{s})$ is a linear combination of $\boldsymbol{\alpha}(t)$ and fixed basis functions $\boldsymbol{f}(\boldsymbol{s})$. It follows from (3) that

$$\operatorname{cov}(\tilde{\xi}(t+\Delta, \boldsymbol{s}), \tilde{\xi}(t, \boldsymbol{s}')) = \boldsymbol{f}^{T}(\boldsymbol{s}) \operatorname{cov}(\boldsymbol{\alpha}(t+\Delta), \boldsymbol{\alpha}(t)) \boldsymbol{f}(\boldsymbol{s}').$$
(6)

Hence, it is sufficient to obtain the covariance structure of the multivariate temporal process

 $\boldsymbol{\alpha}(t)$ given by the following proposition.

Proposition 2. For the multivariate temporal process $\alpha(t)$ defined in (4), we have

$$\operatorname{cov}(\boldsymbol{\alpha}(t+\Delta),\boldsymbol{\alpha}(t)) = \exp(\boldsymbol{G}\Delta) \left(\exp(\boldsymbol{G}t)\boldsymbol{H}_0 \exp^*(\boldsymbol{G}^T t) + \int_0^t \exp(\boldsymbol{G}(t-\tau))\boldsymbol{H} \exp^*(\boldsymbol{G}^T(t-\tau))d\tau \right)^{(T)}$$
(7)

where $\mathbf{H} = \operatorname{diag}(\tilde{h}(\mathbf{k}_j))$ and $\mathbf{H}_0 = \operatorname{diag}(\tilde{h}_0(\mathbf{k}_j))$ are respectively the spectral density of $\tilde{\boldsymbol{\varepsilon}}(t)$ and $\boldsymbol{\alpha}(0)$. When $t \to \infty$, the effect of the initial condition $\boldsymbol{\alpha}(0)$ vanishes and we have

$$\lim_{t \to \infty} \operatorname{cov}(\boldsymbol{\alpha}(t+\Delta), \boldsymbol{\alpha}(t)) = \exp(\boldsymbol{G}\Delta) \int_0^t \exp(\boldsymbol{G}(t-\tau)) \boldsymbol{H} \exp^*(\boldsymbol{G}^T(t-\tau)) d\tau.$$
(8)

Remark. The derivation of (7) is provided in Appendix B. To generate some insights on Proposition 2, we first consider the discrete-time representation of the ODE (4), $\alpha(t + \Delta) = \exp(\mathbf{G}\Delta)\alpha(t) + \mathbf{q}(\Delta)$, where

$$\boldsymbol{q}(\Delta) \sim N\left(\int_{t}^{t+\Delta} \boldsymbol{\beta}(t) dt, \int_{0}^{\Delta} \exp(\boldsymbol{G}(\Delta-\tau)) \boldsymbol{H} \exp^{*}(\boldsymbol{G}^{T}(\Delta-\tau)) d\tau\right)$$
(9)

represents the amount of shift applied to $\boldsymbol{\alpha}(t)$ over a time interval Δ due to both the sourcesink and error processes in (1). Then, under a special case with constant convection, diffusion and decay (i.e., $\vec{\boldsymbol{v}}_s = \vec{\boldsymbol{v}}$, $\boldsymbol{D}_s = \text{diag}(d)$ and $\zeta_s = \zeta$), \boldsymbol{G} becomes a diagonal matrix with its (i, i)th entry being given by $g_{i,i} = -d\boldsymbol{k}_i^T\boldsymbol{k}_i - \zeta - i\vec{\boldsymbol{v}}_s^T\boldsymbol{k}_i$, and the (i, i)th entry of the covariance matrix of $\boldsymbol{q}(\Delta)$ becomes

$$\tilde{h}(\boldsymbol{k}_{i}) \int_{0}^{\Delta} \exp(-(d\boldsymbol{k}_{i}^{T}\boldsymbol{k}_{i}+\zeta+\imath\boldsymbol{\vec{v}}_{s}^{T}\boldsymbol{k}_{i})(\Delta-\tau)) \exp^{*}(-(d\boldsymbol{k}_{i}^{T}\boldsymbol{k}_{i}+\zeta+\imath\boldsymbol{\vec{v}}_{s}^{T}\boldsymbol{k}_{i})(\Delta-\tau))d\tau$$

$$= \frac{\tilde{h}(\boldsymbol{k}_{i})}{2d\boldsymbol{k}_{i}^{T}\boldsymbol{k}_{i}+2\zeta} \left[1-\exp(-(2d\boldsymbol{k}_{i}^{T}\boldsymbol{k}_{i}+2\zeta)\Delta)\right].$$
(10)

Equation (10) indicates that: (i) the uncertainty associated with $\boldsymbol{q}(\Delta)$ does not depend on convection; (ii) for small Δ , d and ζ , (10) can be approximated by $\tilde{h}(\boldsymbol{k}_i)\Delta$ which indicates that the effects of diffusion and decay are small on $\boldsymbol{q}(\Delta)$ within a small time interval Δ ; (iii) when $\Delta \to \infty$, (10) becomes $\tilde{h}(\boldsymbol{k}_i)(2d\boldsymbol{k}_i^T\boldsymbol{k}_i+2\zeta)^{-1}$ which indicates that the diffusion and decay force the spectrum of the noise to decay.

3 Real-Valued Processes on Space-Time Grids

In Section 3, we restrict our attention to an important scenario in scientific and engineering applications: real-valued spatio-temporal processes on space-time grids. For example, the temperature field in a data center server room is sampled by thermal sensors at discrete spatial locations and time intervals, radar or remote sensing images are taken at fixed time intervals and over fixed-size image pixels, etc.

We consider a real-valued process $\xi(t, \mathbf{s})$ defined on a $N_1 \times N_2$ regular spatial grid and at time points $t_1, t_2, ..., t_T$. In particular, the rectangular spatial mesh system is defined by a tensor product of two one-dimensional collocation sets,

$$\mathbb{S} = \boldsymbol{s}_1 \otimes \boldsymbol{s}_2, \tag{11}$$

where s_1 and s_2 are $s_1 = (s_1^{(i)}; s_1^{(i)} = \frac{i}{N_1}, i = 0, \dots, N_1 - 1)$ and $s_2 = (s_2^{(i)}; s_2^{(i)} = \frac{i}{N_2}, i = 0, \dots, N_2 - 1)$. Without loss of generality, N_1 and N_2 are assumed to be even numbers.

3.1 2D Discrete Fourier Transform

The proposed approach is deeply rooted in the 2D discrete Fourier transform (DFT). For a 2D process $x(n_1, n_2)$ at grid points (n_1, n_2) , $n_1 = 0, 2, ..., N_1 - 1$ and $n_2 = 0, 2, ..., N_2 - 1$, the DFT of $x(n_1, n_2)$ is defined as

$$X(k_{1},k_{2}) = \frac{1}{N_{1}N_{2}} \sum_{n_{1}=0}^{N_{1}-1} \sum_{n_{2}=0}^{N_{2}-1} x(n_{1},n_{2}) e^{-i(\frac{2\pi}{N_{1}}n_{1}k_{1}+\frac{2\pi}{N_{2}}n_{2}k_{2})}$$

$$= \frac{1}{N_{1}N_{2}} \sum_{n_{1}} \sum_{n_{2}} x(n_{1},n_{2}) \cos(\frac{2\pi}{N_{1}}n_{1}k_{1}+\frac{2\pi}{N_{2}}n_{2}k_{2}))$$

$$-i\frac{1}{N_{1}N_{2}} \sum_{n_{1}} \sum_{n_{2}} x(n_{1},n_{2}) \sin(\frac{2\pi}{N_{1}}n_{1}k_{1}+\frac{2\pi}{N_{2}}n_{2}k_{2}) \equiv \alpha_{k_{1},k_{2}}^{(R)} - i\alpha_{k_{1},k_{2}}^{(I)}$$

(12)

for $k_1 = -N_1/2 + 1, -N_1/2 + 2, ..., N_1/2$ and $k_2 = -N_2/2 + 1, -N_2/2 + 2, ..., N_2/2$. The inverse transform is also obtained as:

$$x(n_{1},n_{2}) = \sum_{k_{1}=-N_{1}/2+1}^{N_{1}/2} \sum_{k_{2}=-N_{2}/2+1}^{N_{2}/2} X(k_{1},k_{2}) e^{i(\frac{2\pi}{N_{1}}n_{1}k_{1}+\frac{2\pi}{N_{2}}n_{2}k_{2})}$$

$$= \sum_{k_{1}} \sum_{k_{2}} (\alpha_{k_{1},k_{2}}^{(R)} - i\alpha_{k_{1},k_{2}}^{(I)}) \left\{ \cos(\frac{2\pi}{N_{1}}n_{1}k_{1} + \frac{2\pi}{N_{2}}n_{2}k_{2}) + i\sin(\frac{2\pi}{N_{1}}n_{1}k_{1} + \frac{2\pi}{N_{2}}n_{2}k_{2}) \right\}$$
(13)
$$= \sum_{k_{1}} \sum_{k_{2}} \alpha_{k_{1},k_{2}}^{(R)} \cos(\frac{2\pi}{N_{1}}n_{1}k_{1} + \frac{2\pi}{N_{2}}n_{2}k_{2}) + \sum_{k_{1}} \sum_{k_{2}} \alpha_{k_{1},k_{2}}^{(I)} \sin(\frac{2\pi}{N_{1}}n_{1}k_{1} + \frac{2\pi}{N_{2}}n_{2}k_{2}).$$

For real-valued $x(n_1, n_2)$, it is well known that (i.e., rotational symmetry)

$$|X(k_1, k_2)| = |X(-k_1, -k_2)|, \quad \arg X(k_1, k_2) = -\arg X(-k_1, -k_2).$$
(14)

Figure 1: Illustrations of 2D DFT for real-valued processes (top row: the original radar image and the recovered image from the inverse DFT; mid row: the real and imaginary parts of the FFT, $X(k_1, k_2)$; bottom row: the low-frequency region of the real and imaginary parts of $X(k_1, k_2)$, i.e., a zoomed-in view).

As an illustration, Figure 1 shows a 80×80 pixel weather radar image and its 2D DFT. The first row of this figure shows the original image (left) and the recovered image (right) from the inverse DFT; the second row shows the real and imaginary parts of the FFT, $X(k_1, k_2)$, for $k_1, k_2 = -39, -38, ..., 40$; and the bottom row presents a zoomed-in view of the real and imaginary parts of $X(k_1, k_2)$ by only keeping the low-frequency components. For such a real-valued process, the rotational symmetry of the real and imaginary parts of $X(k_1, k_2)$ is clearly seen, i.e., $|X(k_1, k_2)| = |X(-k_1, -k_2)|$ and $\arg X(k_1, k_2) = -\arg X(-k_1, -k_2)$. One key observation from Figure 1 is that the Fourier coefficients corresponding to the high-frequency terms (approximately k > 15) are practically zero, which strongly suggests the possibility of dimension reduction by keeping only the low-frequency components. If it is assumed that the image in Figure 1 is band-limited within [-15, 15], then, the spatial sampling rate in this example (i.e., 1/80) far exceeds the Nyquist rate, which explains why the image can be well reconstructed by inverse FFT.

3.2 The Statistical Model for Real-Valued Processes

The 2D DFT motivates us to approximate a real-valued spatio-temporal process $\xi(t, s)$ by allowing $\alpha_{k_1,k_2}^{(R)}$ and $\alpha_{k_1,k_2}^{(I)}$ to vary over time. Hence, we have

$$\xi(t, \boldsymbol{s}) \approx \sum_{k_1 = -N_1/2+1}^{N_1/2} \sum_{k_2 = -N_2/2+1}^{N_2/2} \alpha_{k_1, k_2}^{(R)}(t) f_{k_1, k_2}^{(R)}(\boldsymbol{s}) + \alpha_{k_1, k_2}^{(I)}(t) f_{k_1, k_2}^{(I)}(\boldsymbol{s})$$
(15)

where $f_{k_1,k_2}^{(R)}(\mathbf{s}) = \cos(2\pi s_1 k_1 + 2\pi s_2 k_2), f_{k_1,k_2}^{(I)}(\mathbf{s}) = \sin(2\pi s_1 k_1 + 2\pi s_2 k_2)$. Recall that, $\xi(t, \mathbf{s})$ is a real-valued process on the rectangular mesh system (11) at time points $t_1, t_2, ..., t_T$.

Because of the rotational symmetry (14), we obtain the following constraints:

$$\alpha_{k_1,k_2}^{(R)}(t) = \alpha_{-k_1+iN_1,-k_2+jN_2}^{(R)}(t), \alpha_{k_1,k_2}^{(I)}(t) = -\alpha_{-k_1+iN_1,-k_2+jN_2}^{(I)}(t), \quad i,j \in \mathbb{N}$$
(16)

and

$$\alpha_{0,0}^{(I)}(t) = \alpha_{0,\frac{N_2}{2}}^{(I)}(t) = \alpha_{\frac{N_1}{2},0}^{(I)}(t) = \alpha_{\frac{N_1}{2},\frac{N_2}{2}}^{(I)}(t) = 0.$$
(17)

The constraints (16) and (17) enable us to re-write (15) as

$$\xi(t, \mathbf{s}) = \sum_{\mathbf{k}\in\Omega_1} \alpha_{\mathbf{k}}^{(R)}(t) f_{\mathbf{k}}^{(R)}(\mathbf{s}) + 2 \sum_{\mathbf{k}\in\Omega_2} \left(\alpha_{\mathbf{k}}^{(R)}(t) f_{\mathbf{k}}^{(R)}(\mathbf{s}) + \alpha_{\mathbf{k}}^{(I)}(t) f_{\mathbf{k}}^{(I)}(\mathbf{s}) \right)$$
(18)

where $\mathbf{k} = (k_1, k_2)$, and the two sets of spatial wavenumbers, Ω_1 and Ω_2 , are defined as:

$$\Omega_{1} = \{(0,0), (0, \frac{N_{2}}{2}), (\frac{N_{1}}{2}, 0), (\frac{N_{1}}{2}, \frac{N_{2}}{2})\}$$

$$\Omega_{2} = \{(k_{1}, k_{2}); k_{1} = 0, 1, ..., \frac{N_{1}}{2}, k_{2} = 0, 1, ..., \frac{N_{2}}{2}\}$$

$$\cup \{(k_{1}, k_{2}); k_{1} = -1, ..., -\frac{N_{1}}{2} + 1, k_{2} = -1, ..., -\frac{N_{2}}{2} + 1\} \setminus \Omega_{1}.$$
(19)

It is easy to see that the dimension of the Fourier coefficients is $N_1 \times N_2$, i.e., the total number of $\alpha^{(R)}$ and $\alpha^{(I)}$ to be determined in (18). In spectral analysis, it is a common practice to further drop the terms corresponding to the highest frequencies, $\frac{N_1}{2}$ and $\frac{N_2}{2}$, in order to achieve the rotational symmetry between all pairs in the wavenumber space. Hence, an alternative approach to (18) is:

$$\xi(t, \boldsymbol{s}) = \left[\alpha_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s})\right]_{\boldsymbol{k}=(0,0)} + 2\sum_{\boldsymbol{k}\in\Omega_3} \left(\alpha_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + \alpha_{\boldsymbol{k}}^{(I)}(t) f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s})\right)$$
(20)

where

$$\Omega_{3} = \{(k_{1}, k_{2}); k_{1} = 0, 1, ..., \frac{N_{1}}{2} - 1, k_{2} = 0, 1, ..., \frac{N_{2}}{2} - 1\} \\ \cup \{(k_{1}, k_{2}); k_{1} = -1, ..., -\frac{N_{1}}{2} + 1, k_{2} = -1, ..., -\frac{N_{2}}{2} + 1\} \setminus \{(0, 0)\}.$$

$$(21)$$

and the dimension of (20) is reduced to $N_1 \times N_2 - N_1 - N_2 + 1$. For example, if $N_1 = N_2 = 80$ as shown in Figure 1, the dimensions of (18) and (20) are respectively 6,400 and 6,241. It is also shown in Figure 1 that the Fourier coefficients corresponding to the high-frequency components are close to zero (i.e., the energy is concentrated in the low-frequency region). Hence, the approximation (20) is well justified.

Figure 2: Fourier basis functions at selected frequencies: $f_{40,40}^{(R)}(\boldsymbol{s}), f_{1,0}^{(R)}(\boldsymbol{s}), \text{and } f_{1,10}^{(I)}(\boldsymbol{s}).$

For the same radar image shown in Figure 1, Figure 2 illustrates the Fourier basis functions at selected frequencies. The left panel shows $f_{40,40}^{(R)}(\mathbf{s})$ with $k_1 = k_2 = 40$ (the last entry in Ω_1), the middle panel shows $f_{1,0}^{(R)}(\mathbf{s})$ with $k_1 = 1$ and $k_2 = 0$ (the 40th entry in Ω_2), and the right panel shows $f_{1,10}^{(I)}(\mathbf{s})$ with $k_1 = 1$ and $k_2 = 10$ (the 50th entry in Ω_2).

Similar to Proposition 1, Proposition 3 establishes the temporal dynamics of $\alpha_{\mathbf{k}}^{(R)}(t)$ and $\alpha_{\mathbf{k}}^{(I)}(t)$ such that the approximated process (18) satisfies the SPDE (1). In the case that the process is approximated by (20), the extension of Proposition 3 is trivial and thus omitted.

Proposition 3. Let $\boldsymbol{\alpha}(t) = (\{\alpha_{\boldsymbol{k}}^{(R)}(t); \boldsymbol{k} \in \Omega_1\}, \{\alpha_{\boldsymbol{k}}^{(R)}(t); \boldsymbol{k} \in \Omega_2\}, \{\alpha_{\boldsymbol{k}}^{(I)}(t); \boldsymbol{k} \in \Omega_2\})^T$ be a collection of spectral coefficients; let $\tilde{\xi}(0, \boldsymbol{s})$ be the initial condition where $\boldsymbol{\alpha}(0) \sim N(0, \boldsymbol{H}_0)$ with $\boldsymbol{H}_0 = \operatorname{diag}(\tilde{h}_0(\boldsymbol{k}))$ being a spectral density; let

$$Q(t, \boldsymbol{s}) = \sum_{\boldsymbol{k} \in \Omega_1} \beta_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + 2 \sum_{\boldsymbol{k} \in \Omega_2} \left\{ \beta_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + \beta_{\boldsymbol{k}}^{(I)}(t) f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s}) \right\}$$
(22)

be the spectral representation of the deterministic source-sink process; let

$$\varepsilon(t, \boldsymbol{s}) = \sum_{\boldsymbol{k}\in\Omega_1} \tilde{\varepsilon}_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + 2 \sum_{\boldsymbol{k}\in\Omega_2} \left\{ \tilde{\varepsilon}_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + \tilde{\varepsilon}_{\boldsymbol{k}}^{(I)}(t) f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s}) \right\}$$
(23)

be the spectral representation of the white-in-time stationary error process, and let $\tilde{\boldsymbol{\varepsilon}}(t) = (\{\tilde{\boldsymbol{\varepsilon}}^{(R)}(t); \boldsymbol{k} \in \Omega_1\}, \{\tilde{\boldsymbol{\varepsilon}}^{(R)}(t); \boldsymbol{k} \in \Omega_2\}, \{\tilde{\boldsymbol{\varepsilon}}^{(I)}(t); \boldsymbol{k} \in \Omega_2\})^T$ be a random noise vector with spectral density $\boldsymbol{H} = \text{diag}(\tilde{h}(\boldsymbol{k}))$. Then, the temporal dynamics of $\alpha_{\boldsymbol{k}}^{(R)}(t)$ and $\alpha_{\boldsymbol{k}}^{(I)}(t)$ is given as follows such that the approximated process (18) satisfies the real-valued SPDE (1):

For
$$\mathbf{k}' \in \Omega_1$$
,

$$\dot{\alpha}_{\mathbf{k}'}^{(R)}(t) = C_{\mathbf{k}}^{-1} \sum_{\mathbf{k}\in\Omega_{1}} \alpha_{\mathbf{k}}^{(R)}(t) \Psi_{1,5,9}(\mathbf{k},\mathbf{k}') + 2C_{\mathbf{k}}^{-1} \sum_{\mathbf{k}\in\Omega_{2}} \alpha_{\mathbf{k}}^{(R)}(t) \Psi_{1,5,9}(\mathbf{k},\mathbf{k}') + 2C_{\mathbf{k}}^{-1} \sum_{\mathbf{k}\in\Omega_{2}} \alpha_{\mathbf{k}}^{(I)}(t) \Psi_{2,6,10}(\mathbf{k},\mathbf{k}') + \beta_{\mathbf{k}'}^{(R)}(t) + \tilde{\boldsymbol{\varepsilon}}_{\mathbf{k}'}^{(R)}(t)$$
(24)

For $\mathbf{k}' \in \Omega_2$,

$$\dot{\alpha}_{\mathbf{k}'}^{(R)}(t) = (2C_{\mathbf{k}})^{-1} \sum_{\mathbf{k}\in\Omega_1} \alpha_{\mathbf{k}}^{(R)}(t) \Psi_{1,5,9}(\mathbf{k},\mathbf{k}') + C_{\mathbf{k}}^{-1} \sum_{\mathbf{k}\in\Omega_2} \alpha_{\mathbf{k}}^{(R)}(t) \Psi_{1,5,9}(\mathbf{k},\mathbf{k}') + C_{\mathbf{k}}^{-1} \sum_{\mathbf{k}\in\Omega_2} \alpha_{\mathbf{k}}^{(I)}(t) \Psi_{2,6,10}(\mathbf{k},\mathbf{k}') + \beta_{\mathbf{k}'}^{(R)}(t) + \tilde{\boldsymbol{\varepsilon}}_{\mathbf{k}'}^{(R)}(t)$$
(25)

$$\dot{\alpha}_{\mathbf{k}'}^{(I)}(t) = (2C_{\mathbf{k}})^{-1} \sum_{\mathbf{k}\in\Omega_{1}} \alpha_{\mathbf{k}}^{(R)}(t) \Psi_{3,7,11}(\mathbf{k},\mathbf{k}') + C_{\mathbf{k}}^{-1} \sum_{\mathbf{k}\in\Omega_{2}} \alpha_{\mathbf{k}}^{(R)}(t) \Psi_{3,7,11}(\mathbf{k},\mathbf{k}') + C_{\mathbf{k}}^{-1} \sum_{\mathbf{k}\in\Omega_{2}} \alpha_{\mathbf{k}}^{(I)}(t) \Psi_{4,8,12}(\mathbf{k},\mathbf{k}') + \beta_{\mathbf{k}'}^{(I)}(t) + \tilde{\boldsymbol{\varepsilon}}_{\mathbf{k}'}^{(I)}(t)$$
(26)

where $\Psi_{1,5,9} = \Psi_1 + \Psi_5 + \Psi_9$, $\Psi_{2,6,10} = \Psi_2 + \Psi_6 + \Psi_{10}$, $\Psi_{3,7,11} = \Psi_3 + \Psi_7 + \Psi_{11}$, $\Psi_{4,8,12} = \Psi_4 + \Psi_8 + \Psi_{12}$, and

$$\begin{split} \Psi_{1}(\boldsymbol{k},\boldsymbol{k}') &= \int \vec{\boldsymbol{v}}_{s}^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s}) f_{\boldsymbol{k}'}^{(R)}(\boldsymbol{s}) d\boldsymbol{s}, \Psi_{2}(\boldsymbol{k},\boldsymbol{k}') = -\int \vec{\boldsymbol{v}}_{s}^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) f_{\boldsymbol{k}'}^{(R)}(\boldsymbol{s}) d\boldsymbol{s}, \\ \Psi_{3}(\boldsymbol{k},\boldsymbol{k}') &= \int \vec{\boldsymbol{v}}_{s}^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s}) f_{\boldsymbol{k}'}^{(I)}(\boldsymbol{s}) d\boldsymbol{s}, \Psi_{4}(\boldsymbol{k},\boldsymbol{k}') = -\int \vec{\boldsymbol{v}}_{s}^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) f_{\boldsymbol{k}'}^{(I)}(\boldsymbol{s}) d\boldsymbol{s}, \\ \Psi_{5}(\boldsymbol{k},\boldsymbol{k}') &= \int (-\tilde{\boldsymbol{k}}^{T} \boldsymbol{D}_{s} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)} - [\nabla \cdot \boldsymbol{D}_{s}]^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(I)}) f_{\boldsymbol{k}'}^{(R)} d\boldsymbol{s}, \\ \Psi_{6}(\boldsymbol{k},\boldsymbol{k}') &= \int (-\tilde{\boldsymbol{k}}^{T} \boldsymbol{D}_{s} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)} - [\nabla \cdot \boldsymbol{D}_{s}]^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)}) f_{\boldsymbol{k}'}^{(I)} d\boldsymbol{s}, \\ \Psi_{7}(\boldsymbol{k},\boldsymbol{k}') &= \int (-\tilde{\boldsymbol{k}}^{T} \boldsymbol{D}_{s} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)} - [\nabla \cdot \boldsymbol{D}_{s}]^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)}) f_{\boldsymbol{k}'}^{(I)} d\boldsymbol{s}, \\ \Psi_{8}(\boldsymbol{k},\boldsymbol{k}') &= \int (-\tilde{\boldsymbol{k}}^{T} \boldsymbol{D}_{s} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)} - [\nabla \cdot \boldsymbol{D}_{s}]^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)}) f_{\boldsymbol{k}'}^{(I)} d\boldsymbol{s}, \\ \Psi_{9}(\boldsymbol{k},\boldsymbol{k}') &= -\int \zeta_{s} f_{\boldsymbol{k}}^{(R)} f_{\boldsymbol{k}'}^{(R)} d\boldsymbol{s}, \Psi_{10}(\boldsymbol{k},\boldsymbol{k}') = -\int \zeta_{s} f_{\boldsymbol{k}}^{(I)} f_{\boldsymbol{k}'}^{(I)} d\boldsymbol{s}, \\ \Psi_{12}(\boldsymbol{k},\boldsymbol{k}') &= -\int \zeta_{s} f_{\boldsymbol{k}}^{(I)} f_{\boldsymbol{k}'}^{(I)} d\boldsymbol{s}, \\ C_{\boldsymbol{k}} &= \int f_{\boldsymbol{k}}^{(R)} f_{\boldsymbol{k}}^{(R)} d\boldsymbol{s} = \int f_{\boldsymbol{k}}^{(I)} f_{\boldsymbol{k}}^{(I)} d\boldsymbol{s}, \text{ and } \tilde{\boldsymbol{k}} = 2\pi \boldsymbol{k}. \end{split}$$

Remark 1 (nonlinear energy transfer between multiple scales). The proof of Proposition 3 can be obtained using the Galerkin method and is provided in Appendix C. In Proposition 3, $\Psi_1, ..., \Psi_4$ determine the transition of the Fourier mode $\alpha_{\mathbf{k}}^{(R)}(t) - i\alpha_{\mathbf{k}}^{(I)}(t)$ due to convection under the velocity field \vec{v}_s . In a special case when \vec{v}_s is constant while the diffusion and source-sink are ignored, the magnitude (i.e., "energy") of each Fourier mode is conserved under $\Psi_1, ..., \Psi_4$ only with shifted argument. This can be clearly shown by letting $\vec{v}_s = \vec{v}$, $D_s = 0, \ \beta_{\mathbf{k}}^{(R)} = \beta_{\mathbf{k}}^{(I)} = \tilde{\boldsymbol{\varepsilon}}_{\mathbf{k}'}^{(R)}(t) = \tilde{\boldsymbol{\varepsilon}}_{\mathbf{k}'}^{(I)}(t) = 0$. Then, for $\mathbf{k}' \in \Omega_2$, we have $\Psi_1 = \Psi_4 = 0$ and $\Psi_2 = -\Psi_3 = -2C_{\mathbf{k}'}\pi\vec{v}\mathbf{k}'$. It follows from (25) and (26) that

$$\dot{\alpha}_{k'}^{(R)}(t) = -2C_{k'}\pi\alpha_{k'}^{(I)}(t)\vec{v}k', \qquad \dot{\alpha}_{k'}^{(I)}(t) = 2C_{k'}\pi\alpha_{k'}^{(R)}(t)\vec{v}k'.$$
(27)

Hence,

$$\frac{d}{dt} \left\{ (\alpha_{\mathbf{k}'}^{(R)}(t))^2 + (\alpha_{\mathbf{k}'}^{(I)}(t))^2 \right\} = 2\alpha_{\mathbf{k}'}^{(R)}(t)\dot{\alpha}_{\mathbf{k}'}^{(R)}(t) + 2\alpha_{\mathbf{k}'}^{(I)}(t)\dot{\alpha}_{\mathbf{k}'}^{(I)}(t)
= 4C_{\mathbf{k}'}\pi\vec{\boldsymbol{v}}\mathbf{k}'(-\alpha_{\mathbf{k}'}^{(I)}(t)\alpha_{\mathbf{k}'}^{(R)}(t) + \alpha_{\mathbf{k}'}^{(I)}(t)\alpha_{\mathbf{k}'}^{(R)}(t)) = 0$$
(28)

which implies the conservation of energy at each Fourier mode $\alpha_{\mathbf{k}}^{(R)}(t) - i\alpha_{\mathbf{k}}^{(I)}(t)$ under the special case with constant convection, and zero diffusion and source-sink.

However, \vec{v}_s varies in space in our paper, and the evolution of multiple Fourier modes must interact with each other as clearly shown in (24)~(26) (also see the remark under Proposition 1). Hence, although the convection under a spatially-varying velocity field \vec{v}_s does not increase nor decrease the total energy within the system, it re-distributes the energy to different Fourier modes causing the non-linear energy transfer between multiple scales.

Remark 2 (*The IDE-based representation*). One important modeling approach to capture the spatio-temporal dynamics relies on the stochastic Integro-Difference Equation (IDE) models (Wikle and Cressie, 1999; Wikle, 2002; Brown et al., 2000; Liu et al., 2016). Assuming discrete time steps with lag Δ , the key idea of the IDE-based model is to describe the spatio-temporal dynamics through integral operations in space:

$$\xi(t, \boldsymbol{s}) = \lambda_{\Delta} \int_{\mathbb{S}} \omega_{\boldsymbol{s}}(\boldsymbol{x}) \xi(t - \Delta, \boldsymbol{x}) d\boldsymbol{x} + \text{noise}$$
⁽²⁹⁾

where λ_{Δ} is a scaling factor and ω is a redistribution kernel. For example, if (29) is a convolution operation, then, ω is the convolution kernel.

Under spatially and temporally invariant convection-diffusion, the link between an IDEbased model (in its limiting case) and the convection-diffusion equation has been established (Brown et al., 2000; Sigrist et al., 2015). Under spatially and temporally varying convectiondiffusion, Liu et al. (2016) adopted the IDE-based model without explicitly establishing the connection between the IDE-based model and convection-diffusion equations.

The following proposition provides the (discretized) IDE-based representation of the SPDE (1) with a *spatially-varying* convection-diffusion operator \mathcal{A}_s . As shown by this proposition, the IDE-based representation can no longer be seen as a spatial convolution operation due to the nonlinear energy transfer between multiple scales discussed in Remark 1 above.

Proposition 4 (a discretized IDE-based representation). For a spatially-varying but temporallyinvariant convection-diffusion operator \mathcal{A} , the convection-diffusion operation $\mathcal{A}\tilde{\xi}(t+\Delta, s)$ on the approximated process $\tilde{\xi}(t+\Delta, s)$ admits a discretized IDE-based representation:

$$\tilde{\xi}(t+\Delta, \boldsymbol{s}) = \frac{1}{N} \sum_{i=1}^{N} \omega_{\boldsymbol{s}}(\boldsymbol{x}_i) \tilde{\xi}(t, \boldsymbol{x}_i)$$
(30)

where $N = N_1 \times N_2$, $\boldsymbol{s} \in \mathbb{S}$, $\boldsymbol{x}_i \in \mathbb{S}$ for i = 1, ..., N, and

$$\omega_{\boldsymbol{s}}(\boldsymbol{x}_i) = \sum_{j}^{N} \sum_{j'}^{N} \left[e^{\boldsymbol{G}\Delta} \right]_{j,j'} e^{i(\boldsymbol{k}_j \boldsymbol{s} - \boldsymbol{k}_{j'} \boldsymbol{x}_i)}.$$
(31)

The proof of Proposition 4 is given in the Appendix D. Note that:

- Although $\omega_s(\boldsymbol{x}_i)$ in (30) can still be interpreted as the re-distribution kernel, (30) is no longer a convolution operation as is often the case in the literature. This is due to the interesting non-linear energy re-distribution across different frequencies. The matrix exponential, $e^{G\Delta}$, is non-diagonal when \mathcal{A} varies in space, and the temporal evolution of the components in $\boldsymbol{\alpha}(t)$ is coupled.
- In a special case when the convection-diffusion operator \mathcal{A} does not vary in space and time, the discrete IDE-based representation in Proposition 4 reduces to a convolution operation. Note that when \mathcal{A} does not vary in space and time, \boldsymbol{G} becomes a diagonal matrix and $\omega_{\boldsymbol{s}}(\boldsymbol{x}_i) = \sum_{j=1}^{N} \mathcal{G}_j e^{i\boldsymbol{k}_j(\boldsymbol{s}-\boldsymbol{x}_i)}$ with $\mathcal{G}_j = -\boldsymbol{k}_j^T \boldsymbol{D} \boldsymbol{k}_j \zeta i \boldsymbol{\vec{v}}^T \boldsymbol{k}_j$ being the *i*th

diagonal component. Hence, (30) reduces to

$$\tilde{\xi}(t+\Delta, \boldsymbol{s}) = \frac{1}{N} \sum_{i=1}^{N} \left[\sum_{j=1}^{N} \mathcal{G}_{j} e^{i \boldsymbol{k}_{j}(\boldsymbol{s}-\boldsymbol{x}_{i})} \right] \tilde{\xi}(t, \boldsymbol{x}_{i})$$

$$= \frac{1}{N} \sum_{i=1}^{N} \omega_{\boldsymbol{s}}(\boldsymbol{x}_{i}) \tilde{\xi}(t, \boldsymbol{x}_{i}).$$
(32)

In such a special case, the dynamics of $\tilde{\xi}(t, s)$ is captured by spatial convolution and is consistent with the existing results in the literature (Wikle and Cressie, 1999; Brown et al., 2000; Liu et al., 2016). In fact, it is easy to see that $\omega_s(\mathbf{x}_i)$ is the inverse Fourier transform of \mathcal{G}_j , and $\omega_s(\mathbf{x}_i)$ is a Gaussian kernel (Section 3.2.1 in Liu et al. (2016)). Of course, in a general case where \mathcal{A} varies in space, the dynamics of $\tilde{\xi}(t, s)$ is captured by (30), which is no longer a convolution operation in space.

Proposition 4 links the proposed model to a large body of literature and provides a different perspective on how the proposed model can be interpreted.

4 Integration with a Dynamical Model

The results obtained in Sections 2 and 3 enable us to embed the physics, governed by the convection-diffusion process (1), into the framework of Hierarchical Spatio-Temporal Models (DSTM) described in Wikle et al. (1998); Cressie and Wikle (2011); Katzfuss et al. (2020). The DSTM has been shown to be effective in handling non-stationary, irregular complex processes with either continuous, discrete or multivariate data, and provides computational advantages for inference, monitoring, prediction and dynamic network design. The DSTM framework consists of a data model, a process model, and a parameter model. The data model can be directly obtained from the spectral decomposition (3) and is given by:

Data Model:
$$\mathbf{Y}(t) = \mathbf{F} \boldsymbol{\alpha}(t) + \mathbf{V}(t)$$
 (33)

where $\mathbf{Y}(t) = (Y_{\mathbf{s}_1}(t), ..., Y_{\mathbf{s}_N}(t))^T$ is a $N \times 1$ vector that contains the data observed at time t, $\boldsymbol{\alpha}(t)$ is a $K \times 1$ vector that contains the spectral coefficients, $\mathbf{F} = (\mathbf{f}(\mathbf{s}_1), \mathbf{f}(\mathbf{s}_2), ..., \mathbf{f}(\mathbf{s}_N))^T$ is a $N \times K$ observation matrix of Fourier functions, and the noise term $\mathbf{V}(t)$ is added to capture the unexplained variation such as observation error.

The process model, which captures the temporal dynamics of $\alpha(t)$, can be obtained from the discrete-time representation of the ODE (4):

Process Model:
$$\boldsymbol{\alpha}(t) = \exp(\boldsymbol{G}\Delta)\boldsymbol{\alpha}(t-\Delta) + \boldsymbol{\beta}(t-\Delta)\Delta + \boldsymbol{W}_{\boldsymbol{\alpha}}(t)$$
 (34)

where $\boldsymbol{W}_{\boldsymbol{\alpha}}(t) \sim N(0, \int_{0}^{\Delta} \exp(\boldsymbol{G}(\Delta - \tau)) \boldsymbol{H} \exp^{*}(\boldsymbol{G}^{T}(\Delta - \tau)) d\tau).$

If necessary, a parameter model can also be included to incorporate prior information or regularizations obtained from other sources, especially the outputs from physical models which are widely available for many spatio-temporal modeling problems. For example, when modeling the temperature field in a data center, information on the velocity field (i.e., air flow) and diffusion matrix can usually be derived from the CFD model and flow sensors. Another example is the modeling of urban air pollution process or the motion of extreme weather systems, information on wind field is usually available from the Numerical Weather Prediction (NWP) models (Liu et al., 2016, 2018; Zhuk et al., 2017).

In the convection-diffusion process (1), Q(t, s) is the deterministic source (i.e., generation) and sink (i.e., destruction) of the quantify of interest. As discussed in Section 2, Q(t, s)admits a spectral representation $Q(t, s) = \mathbf{f}^T(s)\boldsymbol{\beta}(t)$ with $\boldsymbol{\beta}(t) = (\beta^{(1)}(t), ..., \beta^{(K)}(t))^T$ dynamically evolving over time. If an AR(1) process is considered for $\boldsymbol{\beta}(t)$, we obtain

Proposition 5. Under the assumptions $A1 \sim A4$ made in Proposition 1 and consider an AR(1) process for $\boldsymbol{\beta}(t)$ such that $\boldsymbol{\beta}(t) = \boldsymbol{M}_{\Delta}\boldsymbol{\beta}(t-\Delta) + \boldsymbol{W}_{\beta}(t)$ where $\boldsymbol{W}_{\beta}(t) \sim N(0, \tau_{\beta}^{2}\boldsymbol{I}_{K})$ and $\boldsymbol{M}_{\Delta} = \rho_{\Delta}\boldsymbol{I}_{K}$, a dynamical model with local linear growth can be written as:

$$\mathbf{Y}(t) = (\mathbf{F}, \mathbf{0}_{N,K})\boldsymbol{\theta}(t) + \mathbf{V}(t)$$

$$\boldsymbol{\theta}(t) = \tilde{\mathbf{G}}\boldsymbol{\theta}(t - \Delta) + \mathbf{W}(t)$$
(35)

where

$$\tilde{\boldsymbol{G}} = \begin{pmatrix} \exp(\boldsymbol{G}\Delta) & \Delta \boldsymbol{I}_K \\ \hline \boldsymbol{0}_K & \boldsymbol{M}_\Delta \end{pmatrix}$$
(36)

and $\boldsymbol{\theta}(t) = (\boldsymbol{\alpha}(t), \boldsymbol{\beta}(t))^T, \, \boldsymbol{V}(t) \sim N(0, \tau_{\boldsymbol{V}}^2 \boldsymbol{I}_N), \, \boldsymbol{W}(t) = (\boldsymbol{W}_{\boldsymbol{\alpha}}(t), \boldsymbol{W}_{\boldsymbol{\beta}}(t))^T.$

It is easy to see that $\boldsymbol{W}(t) \sim N(0, \boldsymbol{\Sigma}_{\boldsymbol{W}})$, and

$$\boldsymbol{\Sigma}_{\boldsymbol{W}} = \left(\begin{array}{c|c} \int_{0}^{\Delta} \exp(\boldsymbol{G}(\Delta - \tau)) \boldsymbol{H} \exp^{*}(\boldsymbol{G}^{T}(\Delta - \tau)) d\tau & \\ \hline & & \tau_{\boldsymbol{\beta}}^{2} \boldsymbol{I}_{K} \end{array} \right).$$
(37)

For large spatio-temporal data, the traditional geostatistical modeling paradigm is limited due to the prohibitive $\mathcal{O}((TN)^3)$ operations associated with factorizing the dense covariance matrices. The conditioning structure of the proposed DSTM reduces the cubic time complexity to $\mathcal{O}(TN^3)$ if the Kalman filter and FFBS (Forward Filtering and Backward Sampling) are used (Carter and Kohn, 1994). More importantly, since the data process (33) is based on the spectral representation of a spatial process, Sigrist et al. (2015) noted that the Kalman filter can be efficiently performed in the spectral space for gridded data by converting $\mathbf{Y}(t)$ from the physical space to $\tilde{\mathbf{Y}}(t)$ in the spectral space using FFT which requires $\mathcal{O}(TN\log(N))$. Hence, the dynamical model (35) in the spectral space is given by

$$\tilde{\mathbf{Y}}(t) = \tilde{\mathbf{F}}\boldsymbol{\theta}(t) + \tilde{\mathbf{V}}(t)$$

$$\boldsymbol{\theta}(t) = \tilde{\mathbf{G}}\boldsymbol{\theta}(t - \Delta) + \mathbf{W}(t)$$
(38)

where $\tilde{\boldsymbol{Y}}(t)$ is the Fourier transform of $\boldsymbol{Y}(t)$ obtained from FFT, $\tilde{\boldsymbol{F}} = (\boldsymbol{I}_K, \boldsymbol{0}_K)$, and $\tilde{\boldsymbol{V}}(t) \sim N(0, \tau_{\tilde{\boldsymbol{V}}}^2 \boldsymbol{I}_K)$.

Note that the dimensions of $\tilde{\mathbf{Y}}(t)$, $\boldsymbol{\theta}(t)$ and $\tilde{\mathbf{F}}$ are respectively $K \times 1$, $2K \times 1$ and $K \times 2K$. In practice, it is possible to only keep the low frequency components and make K much smaller than N (see Figure 1). Therefore, the choice of K in (3) controls both the dimension and computational cost of the problem.

The Kalman Filter in the spectral domain can be obtained from the classical iterations (West and Harrison, 1997; Petris et al., 2009). Consider a dynamical model specified by (38). Let $\boldsymbol{m}_{t|t-\Delta}$ and $\boldsymbol{m}_{t|t}$ respectively be the one-step-ahead predictive and filtering means of $\boldsymbol{\theta}(t)$, let $\boldsymbol{Q}_{t|t-\Delta}$ and $\boldsymbol{Q}_{t|t}$ respectively be the one-step-ahead predictive and filtering covariance matrices of $\boldsymbol{\theta}(t)$, and let $\boldsymbol{\theta}(0) \sim \mathcal{N}(\boldsymbol{m}_{0|0}, \boldsymbol{Q}_{0|0})$, then, the following statements hold:

The one-step-ahead predictive mean and covariance matrix of $\boldsymbol{\theta}(t)$ are

$$m_{t|t-\Delta} = Gm_{t-\Delta|t-\Delta}$$

$$Q_{t|t-\Delta} = \tilde{G}Q_{t-\Delta|t-\Delta}\tilde{G}^T + \Sigma_W,$$
(39)

and the filtering mean and covariance matrix of $\boldsymbol{\theta}(t)$ are

$$\boldsymbol{m}_{t|t} = \tilde{\boldsymbol{G}} \boldsymbol{m}_{t|t-\Delta} + \boldsymbol{Q}_{t|t-\Delta}^{[1:2K,1:K]} (\boldsymbol{Q}_{t|t-\Delta}^{[1:K,1:K]} + \tau_{\tilde{\boldsymbol{V}}} \boldsymbol{I}_K)^{-1} (\tilde{\boldsymbol{Y}}(t) - \boldsymbol{m}_{t|t-\Delta}^{[1:K,1]}) \boldsymbol{Q}_{t|t} = \boldsymbol{Q}_{t|t-\Delta} - \boldsymbol{Q}_{t|t-\Delta}^{[1:2K,1:K]} (\boldsymbol{Q}_{t|t-\Delta}^{[1:K,1:K]} + \tau_{\tilde{\boldsymbol{V}}} \boldsymbol{I}_K)^{-1} \boldsymbol{Q}_{t|t-\Delta}^{[1:K,1:2K]}.$$
(40)

Here, $\cdot^{[1:K_1,1:K_2]}$ returns the first K_1 rows and K_2 columns of a matrix, $\tilde{F}Q_{t|t-\Delta}\tilde{F}^T = Q_{t|t-\Delta}^{[1:K,1:K]}$, $Q_{t|t-\Delta}\tilde{F}^T = Q_{t|t-\Delta}^{[1:2K,1:K]}$, $\tilde{F}Q_{t|t-\Delta} = Q_{t|t-\Delta}^{[1:K,1:2K]}$ and $\tilde{F}m_{t|t-\Delta} = m_{t|t-\Delta}^{[1:K,1]}$.

The dynamical models (35) and (38) can be extended to non-Gaussian models, and the Sequential Monte Carlo (SMC) method can then be used; see Appendix E for a GPU-accelerated SMC algorithm.

The dynamical model (38) contains a large number of unknown parameters: (i) the velocity field \vec{v}_s , diffusivity D_s , and decay ζ_s which vary in space; (ii) ρ_{Δ} and τ_{β} defined above (35); (iii) the spectral density $H = \text{diag}(\tilde{h}(k_j))$ of $\tilde{\varepsilon}(t)$; and (iv) $\tau_{\tilde{V}}$. Here, \vec{v}_s , D_s , ζ_s and ρ_{Δ} are needed for computing \tilde{G} in (36), ρ_{Δ} and H are needed for evaluating the covariance matrix Σ_W , and $\tau_{\tilde{V}}$ determines the covariance matrix of \tilde{V} .

The log-likelihood function can be constructed based on the one-step-ahead predictive distribution of $\tilde{Y}(t)$ obtained from the Kalman Filter iterations:

$$l = -\frac{1}{2} \sum_{t=1}^{T} \log \det(\boldsymbol{Q}_{t|t-\Delta}^{[1:K,1:K]} + \tau_{\tilde{\boldsymbol{V}}} \boldsymbol{I}_{K}) - \frac{1}{2} (\tilde{Y}(t) - \boldsymbol{m}_{t|t-\Delta}^{[1:K]})^{T} (\boldsymbol{Q}_{t|t-\Delta}^{[1:K,1:K]} + \tau_{\tilde{\boldsymbol{V}}} \boldsymbol{I}_{K})^{-1} (\tilde{Y}(t) - \boldsymbol{m}_{t|t-\Delta}^{[1:K]}).$$
(41)

Note that the problem apparently becomes intractable if we allow the velocity \vec{v}_s , dif-

fusivity D_s , and decay ζ_s to arbitrarily vary in the spatial domain. Hence, it is necessary to impose some assumptions (such as spatial smoothness) on \vec{v}_s , D_s and ζ_s . In this paper, we consider a flexible locally weighted mixture of linear regression models (Stroud et al., 2001) for the velocity \vec{v}_s , although other modeling approaches are possible depending on the problem of interest. Let $v_s^{(x)}$ and $v_s^{(y)}$ respectively be the horizontal and vertical components of the velocity vector \vec{v}_s at s, and let $v^{(\max)} > 0$ be the specified maximum speed magnitude, we assume

$$v_{\boldsymbol{s}}^{(x)} = v^{(\max)} \tanh\left\{\sum_{j=1}^{J} \pi_j(\boldsymbol{s}) \boldsymbol{b}_j^T(\boldsymbol{s}) \boldsymbol{\gamma}_j^{(x)}\right\}, \quad v_{\boldsymbol{s}}^{(y)} = v^{(\max)} \tanh\left\{\sum_{j=1}^{J} \pi_j(\boldsymbol{s}) \boldsymbol{b}_j^T(\boldsymbol{s}) \boldsymbol{\gamma}_j^{(y)}\right\} \quad (42)$$

where $\boldsymbol{b}_j(\boldsymbol{s})$ is a column vector of known basis functions, $\boldsymbol{\gamma}_j^{(x)}$ and $\boldsymbol{\gamma}_j^{(y)}$ are column vectors of unknown parameters, and π_j is a non-negative kernel centered at chosen locations. Note that, the hyperbolic tangent, $\tanh(\cdot)$, is used to bound both $|v_s^{(x)}|$ and $|v_s^{(y)}|$ within $[-v^{(\max)}, v^{(\max)}]$.

Let $\boldsymbol{v}^{(x)} = (v_{\boldsymbol{s}_1}^{(x)}, ..., v_{\boldsymbol{s}_N}^{(x)})^T$, $\boldsymbol{v}^{(y)} = (v_{\boldsymbol{s}_1}^{(y)}, ..., v_{\boldsymbol{s}_N}^{(y)})^T$, $\boldsymbol{B}_j = (\boldsymbol{b}_j(\boldsymbol{s}_1), ..., \boldsymbol{b}_j(\boldsymbol{s}_N))$ and $\boldsymbol{\pi}_j = (\pi_j(\boldsymbol{s}_1), ..., \pi_j(\boldsymbol{s}_N))$, we have

$$\boldsymbol{v}^{(x)} = \boldsymbol{v}^{(\max)} \tanh \left\{ (\operatorname{diag}(\boldsymbol{\pi}_1)\boldsymbol{B}_1, ..., \operatorname{diag}(\boldsymbol{\pi}_J)\boldsymbol{B}_J) \begin{pmatrix} \boldsymbol{\gamma}_1^{(x)} \\ \vdots \\ \boldsymbol{\gamma}_J^{(x)} \end{pmatrix} \right\}$$

$$\boldsymbol{v}^{(y)} = \boldsymbol{v}^{(\max)} \tanh \left\{ (\operatorname{diag}(\boldsymbol{\pi}_1)\boldsymbol{B}_1, ..., \operatorname{diag}(\boldsymbol{\pi}_J)\boldsymbol{B}_J) \begin{pmatrix} \boldsymbol{\gamma}_1^{(y)} \\ \vdots \\ \boldsymbol{\gamma}_J^{(y)} \end{pmatrix} \right\}.$$
(43)

Similarly, it is possible to model the decay ζ_s based on the same idea. The diffusivity D_s usually depends on the velocity field \vec{v}_s through some functions motivated by fundamental physics. For some applications, prior information about \vec{v}_s , D_s , and ζ_s is available. For example, in the modeling of weather systems, the velocity, diffusivity and decay can be generated from the Numerical Weather Prediction models. For another example, in the modeling of the temperature field in a DC computer room, the air flow can be obtained from the Navier-Stokes equations. Hence, it is sometimes possible to treat \vec{v}_s , D_s and ζ_s as known, or, incorporate the prior knowledge on these parameters in a Bayesian framework.

Compared with existing approaches, such as Stroud et al. (2010), the proposed approach can be viewed as a more intrusive statistical version of a reduced-order physics model. The proposed model is built upon the solution (in the frequency domain) of the convectiondiffusion equations, and the output from our statistical model remains within the solution space of the physical model (i.e., the SPDE (1)). The physical model is integrated into a statistical modeling framework with all parameters being estimated from data. A less intrusive approach that integrates the physical model outputs and measurement data are available in Stroud et al. (2010), which requires some key physical parameters (velocity,

diffusion and forcing) to be found before they are integrated into the statistical model.

Figure 3: The data set (simulated from (1)) used for the numerical example. The panel on the left shows the initial condition and a spatially-varying velocity field. The figures on the right show the images for t = 1, 2, ..., 10.

5 Numerical Example and Case Study

A numerical example is presented in Section 5.1 to investigate the basic properties and generate some critical insights of the proposed approach. A case study is followed in Section 5.2 to illustrate the application of the proposed method on the modeling of weather radar image data for tropical thunderstorms.

5.1 Numerical Example

The numerical example is based on a simulated spatio-temporal data set shown in Figure 3. The data are generated from the SPDE (1) on a 20 × 20 gridded spatial area for t = 0, 1, ..., 10. Both the initial condition (t = 0) and velocity field \vec{v}_s are shown on the left panel of Figure 3. The velocity vectors vary over the spatial domain, and a small *vortex* is created in the southeast region to test the capabilities of the proposed model in capturing such complexities. The diffusivity D_s is set to an identify matrix. The decay ζ is set to a constant 0.9. The error process $\varepsilon(t, s)$ is generated by $f^T(s)\tilde{\varepsilon}(t)$ where $\tilde{\varepsilon}(t)$ is a random

vector with the spectral density $0.05I_K$. A spatially-varying source-sink term Q(s, t) is also included in the process.

The model parameters are estimated by MLE. Here, the velocity field is modeled by (43) with J = 4 and $v^{(\text{max})} = 0.19$, which is approximately one fifth of the width of the spatial domain in the horizontal or vertical direction. Note that, in the absence of any prior knowledge on the velocity field, the four kernels are uniformly allocated over the spatial domain: (0.225, 0.225), (0.725, 0.725), (0.225, 0.725), (0.725, 0.225). When prior knowledge on the velocity field is available as in some applications, such knowledge can guide us to appropriately place the kernels. In radar-based precipitation nowcasting, for example, information on wind field can be obtained from Numerical Weather Predictions and more kernels can be placed to areas where the variability of wind is expected to be high.

Figure 4 shows the actual and estimated velocity fields. The centers of the four kernels in (43) are also shown in the figure. We see that the proposed approach accurately estimates the velocity field which varies in the spatial domain. In particular, the small *vortex* in the southeast region is successfully captured, demonstrating the capabilities of the proposed approach in modeling spatio-temporal data arising from a physical process (1) under a spatially-varying velocity field. The Kalman Filter in spectral domain (Proposition 5) is used to obtained the filtered θ , which is a 361 × 1 vector in the dynamical model (38). Then, inverse Fourier transform is applied to construct the filtered images, and the reconstructed images at times t = 2, 4, 6, 8, 10 are shown in Figure 5.

Figure 4: Actual (left) and estimated (right) velocity fields

Figure 5: Actual (top row) and filtered (bottom row) images at times 2, 4, 6, 8 and 10.

5.2 Case Study: Radar-Based Weather System Modeling

Following the numerical example, a case study is presented in which the proposed method is used to model highly chaotic weather systems—tropical thunderstorms—based on weather radar images. Weather radar echoes, correlated in both space and time, provide a rich source of information for short-term precipitation nowcasting. In the meteorological community, the methods which are used to perform spatio-temporal extrapolation/advection of radar reflectivity (echo) field are collectively known as the radar-based Quantitative Precipitation Forecasts (QPF) (RMI, 2008).

5.2.1 Basic Settings and Data Processing

Figure 6 (the top row) shows a sequence of radar images obtained from a dual polarization Meteorological Doppler Weather Radar (MDWR) system. Each image contains the standard Constant Altitude Plan Position Indicator (CAPPI) reflectivity data at 1 km above the mean sea level. The legend shows the precipitation rate (mm/hr) converted from the CAPPI data using the Marshall-Palmer relationship. It is possible to see that the thunderstorm is moving from west to east driven by a velocity (wind) field, which is not directly observable.

The images are generated at 5-min intervals and on a Cartesian 2D grid of 200×200 pixels. The centers of two neighboring pixels are approximately 0.5km apart, and the spatial area covered by an image is approximately $100 \times 100 \text{km}^2$. The radar images are obtained from Singapore—a tropical island city-state which occupies approximately a $40 \times 20 \text{km}^2$ spatial area in the center of the image; see Figure 7. Hence, in the horizontal and vertical directions, the dimensions of the area covered by a radar image are respectively 2.5 and 5 times larger than the dimensions of the spatial area of interest. There are three reasons why this setting is necessary: 1) It is known that the 2D DFT suffers from the edge-effects when it is applied to non-periodic images, such as the cross-shaped artifacts in the frequency domain due to spectral leakage. This issue has been extensively discussed in Guinness and Fuentes (2017) and Guinness (2019) from the perspective of statistical modeling; 2) Since the radar-based

Figure 6: A tropical thunderstorm system on a doppler weather radar system at t = 1, 2, ..., 6. Top row: original CAPPI reflectivity data at 1 km above the mean sea level; Bottom row: low-pass filtered images (threshold: 30 radians per unit distance)

QPF in the meteorological society essentially relies on the spatio-temporal extrapolation of radar reflectivity field, it is impossible to predict the reflectivity at the (influx) boundaries, where the weather system moves into the range of a radar image; 3) If the entire spatial area covered by a radar image is of interest, then, it is necessary to consider the boundary conditions of the SPDE (1) which are unknown and uncontrollable in this case study. For the three reasons above, the modeling and prediction results are less reliable at the boundaries of the images, and embedding the spatial area of interest (which is much smaller) at the center of the radar image (computational domain) effectively mitigates this boundary issue in practice.

As tropical storms are highly chaotic with small-scale localized convective cells, radar images at pixel levels are noisy and non-smooth. Hence, we perform FFT on the original images and reconstruct the low-pass filtered images by only retaining the low-frequency components whose (absolute) angular wavenumber is less than or equal 30 radians per unit distance in both directions. The low-pass filtered images, shown in the bottom row of Figure 6, are used for estimating the unknown model parameters including the wind field. Note that, the original DSTM framework does not necessarily require such a pre-processing of input images (Cressie and Wikle, 2011). For this particular application, the computational bottleneck is to estimate the spatially-varying wind field which determines the matrix G. Given the large spatial coverage of a radar image (10,000km² in this example), the small-scale chaotic local wind patterns are usually not of our main concern. Hence, keeping only the low-frequency terms reduces the computational time and allows us to capture the dominant motion of the weather system over a relatively large spatial domain. Appendix E provides detailed discussions on the computational aspects of the proposed approach.

Figure 7: The spatial area of interest (covered by the rectangle) and the area covered by a radar image. The dimensions of the area covered by a radar image are approximately 2.5 and 5 times larger than the dimensions of the spatial area of interest, respectively in the horizontal and vertical directions.

Figure 8: Observed and filtered images at selected times, t = 1, 3, 5, with the estimated spatially-varying wind field (km/5 min).

5.2.2 Numerical Results

Figure 8 shows both the observed and filtered images at selected times, t = 1, 3, 5. The estimated spatially-varying wind field is also included in the filtered images. It can be seen

that the estimated wind field explains the west-to-east motion of the weather system, which is consistent with our initial observation. It is important to note that, for tropical areas where trade winds from both hemispheres meet (known as the Inter-tropical Convergence Zone), the wind fields near the equator are typically highly variable in space and is captured by the proposed approach.

For tropical thunderstorms, the growth and decay of radar reflectivity become more prominent due to the presence of many small-scale localized convective storm cells embedded in the storm systems. The strong solar heating of land areas in tropical areas causes a phenomenon known as the convective heating, which causes the land areas to become heated more than its surroundings, and leads to significant evaporation that creates the small-scale localized convective weather cells. For such a weather system, heavy thunderstorms can develop, grow, and dissipate very suddenly in a random manner. The lifetime of convective thunderstorm cells can be as short as tens of minutes, posing a tremendous challenge to the spatio-temporal modeling of radar reflectivity data. It has been pointed out that the errors in the linear extrapolation of radar echo fields assuming a persistent reflectivity level are mainly due to the growth and decay of reflectivity (Browning et al., 1982). In addition, the rapid growth-decay of weather systems also makes the NWP models ineffective in predicting the exact location and intensity of individual thunderstorms (RMI, 2008). The proposed spatio-temporal model, on the other hand, has the capability to capture the growth-decay of radar reflectivity in space and time. Note that, the proposed approach is motivated from the SPDE (1) with a source-sink component Q(s,t), and the dynamical model (38) incorporates the source-sink component as an AR(1) process. Figure 9 shows the estimated spatial growth-dissipation of the weather system at selected times, t = 2, 4, 6. These images are reconstructed by the inverse Fourier transform using the filtered $\theta(t)$.

The dynamical model (38) also enables us to perform short-term spatio-temporal extrapolation of the radar reflectivity, i.e., short-term precipitation nowcasting. Note that, in tropical areas, radar images are not used for mid-range or long-term predictions as tropical thunderstorm systems develop quickly and are of very short lifespan. For example, the official lead time for heavy storm warnings is usually between 15 and 45 minutes in tropical countries such as Singapore (NEA, 2017). Figure 10 shows both the actual and 5-, 15- and 25-minute-ahead nowcasting based on our model. The spatio-temporal extrapolation of the weather system reasonably matches with the observed reflectivity fields. The nowcasting accuracy gradually deteriorates as the prediction horizon increases, which is expected given the chaotic nature of tropical weather systems.

Comparison studies are performed between the proposed method and two other methods in the literature. The first method is a well-known radar-based short-term precipitation prediction approach known as COTREC (Tracking Radar Echoes by Correlation), and has been widely implemented by the meteorological community (Li and Lai, 2004). COTREC is a typical pattern-based method based on the concept of area tracking. Tracking areas (image pixel arrays) are defined around all pixel grid points, and corresponding areas are searched in the next image by maximizing the cross-correlation between areas. Then, the velocity field can be constructed given the spatial lags between areas and the time lag between

Figure 9: Observed images (top) and estimated growth-dissipation (bottom) of the weather system in space and at selected times, t = 2, 4, 6.

Figure 10: Actual and predicted images for 5-, 15-, and 25-minute-ahead nowcasting.

two images. Unlike the first-order-variation-based methods (e.g. Optical Flow (Horn and Schunck, 1981)), pattern-based methods assume that the shape of image brightness patterns within defined areas do not change over short time intervals. The second method in the comparison study is a recently proposed spatio-temporal conditional autoregressive model under the Lagrangian integration scheme (Liu et al., 2018). We respectively denote these two methods by COTREC2004 and LGK2018.

Table 1: MSE for 5- to 30-minute-ahead nowcasting based on 199 storm events

Table 1 presents the comparison between the proposed methods (assuming both spatiallyvarying and spatially-invariant convection-diffusion operators), COTREC2004 and LGK2018. The Mean-Squared-Error (MSE) is reported for 5-minute- to 30-minute-ahead nowcasting of the (low-pass) radar images based on 199 tropical storm events recorded in 2010 and 2011. It is seen that the proposed method assuming spatially-varying convection-diffusion outperforms the same approach assuming spatially-invariant convection-diffusion, COTREC2004, and LGK2018. This advantage is primarily due to the improvement in estimating the wind field by the proposed method. Both COTREC2004 and LGK2018 estimate the wind field using the pattern-based methods that require the shape of radar images do not change over short time intervals within the defined tracking areas. This assumption is often violated by highly dynamic tropical thunderstorms. In addition, the assumption of spatiallyinvariant convection-diffusion is obviously inappropriate, causing a rapid increase of MSE as the nowcasting horizon grows. Such observations demonstrate the significance of incorporating spatially-varying convection-diffusion in this work.

5.2.3 Discussions on the Periodicity Assumption

When the proposed method is implemented, it is important to note that the choice of the Fourier basis functions is only optimal when the process $\xi(t, s)$ is periodic. Hence, for the three reasons discussed in Section 5.2.1, it is always necessary to embed the spatial area of interest into a larger computational spatial domain. In this section, we provide the readers with additional insights on the effect of the periodicity assumption, if the spatial domain of interest is not embedded into a larger computational domain.

At a chosen point of time t_0 , Figure 11 shows the actual (top row) and forecast (bottom row) weather radar images after 5, 20 and 35 minutes. The time t_0 is so chosen that the weather system is moving out of the boundary of the spatial domain from the southeast corner (as seen in the first row). However, due to the periodicity assumption, the predicted weather system moves back into the spatial domain as indicated by the red arrows. This numerical example strongly justifies the importance of embedding the spatial domain of interest into a bigger computational domain when the proposed approach is adopted. In fact, the extrapolation nature of radar-based precipitation forecast determines that it is impossible to predict the radar reflectivity at the influx boundaries of the spatial domain.

Figure 11: Illustration of the effect of the periodicity assumption when the spatial domain of interest is not embedded into a bigger computational domain. The top and bottom rows, respectively, show the actual and predicted radar images after 5, 20 and 35 minutes. The red arrows indicate that the predicted weather system moves back into the spatial domain precisely due to the periodicity assumption, while the actual weather system leaves the spatial domain.

6 Conclusions

This paper proposed a statistical modeling approach for spatio-temporal data arising from a class of physical convection-diffusion processes. Motivated by existing results in the literature, the proposed approach is rooted in the spectrum decomposition of spatio-temporal processes. However, unlike existing results, this paper obtained the statistical model by considering spatially-varying convection-diffusion and nonzero-mean source-sink. Due to the spatially-varying convection-diffusion, the temporal evolution of individual spectrum coefficients is coupled, which extends the existing results to a more complicated but realistic scenario. This phenomenon is known as the non-linear energy transfer across multiple scales due to spatially-varying convection-diffusion. As a result, the proposed spatio-temporal model has a non-stationary covariance structure which has been established by our theoretical investigation. A dynamical model, in the spectral domain, has been constructed and the conditional structure of the dynamical model leads to tremendous advantages in statistical inference and computation. The proposed approach has been illustrated by a numerical example as well as a case study based on real datasets. The advantages of the proposed method have been demonstrated through a comparison study involving 199 storm events. Note that, since the convection-diffusion processes can be widely found in interdisciplinary domains including environmental sciences, image analysis, geology, material science, reliability engineering, etc., the proposed method has the potential to impact a spectrum of scientific and engineering applications. The R code is available at GitHub: https://github.com/dnncode/Spatio-Temporal-Model-for-SPDE.

7 Appendices

A Proof of Proposition 1

Since $\vec{v}_s^T \nabla f_j(s) = \imath \vec{v}_s^T k_j f_j(s)$ and $\nabla \cdot [D_s \nabla f_j(s)] = (-k_j^T D_s k_j + \imath [\nabla \cdot D_s]^T k_j) f_j(s)$, substituting the spectral decomposition (3) into the SPDE (1) yields:

$$\sum_{j}^{K} f_{j}(\boldsymbol{s})\dot{\alpha}_{j}(t) = -\sum_{j}^{K} i \boldsymbol{\vec{v}}_{\boldsymbol{s}}^{T} \boldsymbol{k}_{j} f_{j}(\boldsymbol{s}) \alpha_{j}(t) + \sum_{j}^{K} (-\boldsymbol{k}_{j}^{T} \boldsymbol{D}_{\boldsymbol{s}} \boldsymbol{k}_{j} + i [\nabla \cdot \boldsymbol{D}_{\boldsymbol{s}}]^{T} \boldsymbol{k}_{j}) f_{j}(\boldsymbol{s}) \alpha_{j}(t) - \zeta_{\boldsymbol{s}} \sum_{j}^{K} f_{j}(\boldsymbol{s}) \alpha_{j}(t) + \sum_{j}^{K} f_{j}(\boldsymbol{s}) \beta_{j}(t) + \sum_{j}^{K} f_{j}(\boldsymbol{s}) \tilde{\varepsilon}_{j}(t).$$

$$(44)$$

Using the Galerkin method, we multiply both the left hand side (LHS) and right hand side (RHS) of (44) by the complex conjugate $f_l^*(\mathbf{s})$ (l = 1, 2, ..., K), and integrate the product over the spatial domain. Because the Fourier basis functions are orthogonal, i.e., $\int f_j(\mathbf{s}) f_l^*(\mathbf{s}) d\mathbf{s} = 0$ if $j \neq l$, the LHS of (44) becomes

$$\int_{\mathbb{S}} \sum_{j=1}^{K} f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) \dot{\alpha}_{j}(t) d\boldsymbol{s} = \dot{\alpha}_{l}(t) \int_{\mathbb{S}} f_{j}(\boldsymbol{s}) f_{j}^{*}(\boldsymbol{s}) d\boldsymbol{s} \equiv \dot{\alpha}_{l}(t) C_{j}$$
(45)

for l = 1, 2, ..., K.

Similarly, for any l = 1, 2, ..., K, we multiply the complex conjugate $f_l^*(s)$ to the RHS of (44) and integrate the product over the spatial domain. Then, the five terms on the RHS

are respectively given by

$$\int_{\mathbb{S}} -\sum_{j}^{K} \imath \vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T} \boldsymbol{k}_{j} f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) \alpha_{j}(t) d\boldsymbol{s} = \sum_{j}^{K} \left(-\imath \int \vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T} \boldsymbol{k}_{j} f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) d\boldsymbol{s} \right) \alpha_{j}(t) \equiv \sum_{j}^{K} g_{l,j}^{(1)} \alpha_{j}(t)$$

$$(46)$$

$$\int_{\mathbb{S}} \sum_{j}^{K} (-\boldsymbol{k}_{j}^{T} \boldsymbol{D}_{\boldsymbol{s}} \boldsymbol{k}_{j} + \imath [\nabla \cdot \boldsymbol{D}_{\boldsymbol{s}}]^{T} \boldsymbol{k}_{j}) f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) \alpha_{j}(t) d\boldsymbol{s}$$

$$= \sum_{j}^{K} \left(\int (-\boldsymbol{k}_{j}^{T} \boldsymbol{D}_{\boldsymbol{s}} \boldsymbol{k}_{j} + \imath [\nabla \cdot \boldsymbol{D}_{\boldsymbol{s}}]^{T} \boldsymbol{k}_{j}) f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) d\boldsymbol{s} \right) \alpha_{j}(t)$$

$$\equiv \sum_{j}^{K} g_{l,j}^{(2)} \alpha_{j}(t)$$
(47)

$$\int_{\mathbb{S}} \sum_{j}^{K} \zeta_{\boldsymbol{s}} f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) \alpha_{j}(t) d\boldsymbol{s} = \sum_{j}^{K} \left(\int \zeta_{\boldsymbol{s}} f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) d\boldsymbol{s} \right) \alpha_{j}(t) \equiv \sum_{j}^{K} g_{l,j}^{(3)} \alpha_{j}(t)$$
(48)

$$\int_{\mathbb{S}} \sum_{j=1}^{K} f_j(\boldsymbol{s}) f_l^*(\boldsymbol{s}) \beta_j(t) d\boldsymbol{s} = C_j \beta_l(t)$$
(49)

$$\int_{\mathbb{S}} \sum_{j}^{K} f_{j}(\boldsymbol{s}) f_{l}^{*}(\boldsymbol{s}) \tilde{\varepsilon}_{j}(t) d\boldsymbol{s} = C_{j} \tilde{\varepsilon}_{l}(t)$$
(50)

Let $g_{i,j} = C_j^{-1}(g_{i,j}^{(1)} + g_{i,j}^{(2)} + g_{i,j}^{(3)})$, we obtain

$$\dot{\alpha}_{l}(t) = \sum_{j}^{K} g_{l,j} \alpha_{j}(t) + \beta_{l}(t) + \tilde{\varepsilon}_{l}(t)$$
(51)

which implies $\dot{\boldsymbol{\alpha}}(t) = \boldsymbol{G}\boldsymbol{\alpha}(t) + \boldsymbol{\beta}(t) + \tilde{\boldsymbol{\varepsilon}}(t)$, as was to be proved

B Proof of Proposition 2

Solving the ODE (4) for discrete time points yields

$$\boldsymbol{\alpha}(t+\Delta) = \exp(\boldsymbol{G}\Delta)\boldsymbol{\alpha}(t) + \boldsymbol{q}(\Delta)$$
(52)

where

$$\boldsymbol{q}(\Delta) \sim N\left(\int_{t}^{t+\Delta} \boldsymbol{\beta}(t) dt, \int_{0}^{\Delta} \exp(\boldsymbol{G}(\Delta-\tau)) \boldsymbol{H} \exp^{*}(\boldsymbol{G}^{T}(\Delta-\tau)) d\tau\right).$$
(53)

Hence, the covariance matrix of $\boldsymbol{\alpha}(t)$ is

$$\operatorname{var}(\boldsymbol{\alpha}(t)) = \exp(\boldsymbol{G}t)\boldsymbol{H}_0 \exp^*(\boldsymbol{G}^T t) + \int_0^t \exp(\boldsymbol{G}(t-\tau))\boldsymbol{H} \exp^*(\boldsymbol{G}^T(t-\tau))d\tau.$$
(54)

It is also noted that

$$cov(\boldsymbol{\alpha}(t+\Delta),\boldsymbol{\alpha}(t)) = cov(exp(\boldsymbol{G}\Delta)\boldsymbol{\alpha}(t) + \boldsymbol{q}(\Delta),\boldsymbol{\alpha}(t))$$

= exp(\boldsymbol{G}\Delta)var(\boldsymbol{\alpha}(t)). (55)

Substituting (54) into (55) immediately implies (7).

C Proof of proposition 3

Note that, $\vec{v}_s^T \nabla f_k^{(R)}(s) = -\vec{v}_s^T \tilde{k} f_k^{(I)}(s)$, $\vec{v}_s^T \nabla f_k^{(I)}(s) = \vec{v}_s^T \tilde{k} f_k^{(R)}(s)$, $\nabla \cdot [D_s \nabla f_k^{(R)}(s)] = -\tilde{k}^T D_s \tilde{k} f_k^{(R)}(s) - [\nabla \cdot D_s]^T \tilde{k} f_k^{(I)}(s)$, and $\nabla \cdot [D_s \nabla f_k^{(I)}(s)] = -\tilde{k}^T D_s \tilde{k} f_k^{(I)}(s) + [\nabla \cdot D_s]^T \tilde{k} f_k^{(R)}(s)$. Then, based on the Galerkin projection, we respectively multiply the LHS of the SPDE (1) by $f_{k'}^{(R)}(s)$ and $f_{k'}^{(I)}(s)$ for $k' \in \Omega_1 \cup \Omega_2$, and integrate the product over the spatial domain. Then, the LHS of (1) becomes

$$\int_{\mathbb{S}} \frac{\partial}{\partial t} \xi(t, \boldsymbol{s}) f_{\boldsymbol{k}'}^{(R)}(\boldsymbol{s}) d\boldsymbol{s}
= \int_{\mathbb{S}} \left(\sum_{\boldsymbol{k} \in \Omega_{1}} \dot{\alpha}_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} (\dot{\alpha}_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + \dot{\alpha}_{\boldsymbol{k}}^{(I)}(t) f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s})) \right) f_{\boldsymbol{k}'}^{(R)}(\boldsymbol{s}) d\boldsymbol{s} \qquad (56)$$

$$= \begin{cases} C_{\boldsymbol{k}} \dot{\alpha}_{\boldsymbol{k}'}^{(R)}(t) & \text{for } \boldsymbol{k}' \in \Omega_{1} \\ 2C_{\boldsymbol{k}} \dot{\alpha}_{\boldsymbol{k}'}^{(R)}(t) & \text{for } \boldsymbol{k}' \in \Omega_{2} \end{cases}$$

and

$$\int_{\mathbb{S}} \frac{\partial}{\partial t} \xi(t, \boldsymbol{s}) f_{\boldsymbol{k}'}^{(I)}(\boldsymbol{s}) d\boldsymbol{s}
= \int_{\mathbb{S}} \left(\sum_{\boldsymbol{k} \in \Omega_{1}} \dot{\alpha}_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} (\dot{\alpha}_{\boldsymbol{k}}^{(R)}(t) f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s}) + \dot{\alpha}_{\boldsymbol{k}}^{(I)}(t) f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s})) \right) f_{\boldsymbol{k}'}^{(I)}(\boldsymbol{s}) d\boldsymbol{s} \qquad (57)
= \begin{cases} 0 & \text{for } \boldsymbol{k}' \in \Omega_{1} \\ 2C_{\boldsymbol{k}} \dot{\alpha}_{\boldsymbol{k}'}^{(I)}(t) & \text{for } \boldsymbol{k}' \in \Omega_{2} \end{cases}$$

Similarly, we respectively multiply the RHS of the SPDE (1) by $f_{\mathbf{k}'}^{(R)}(\mathbf{s})$ and $f_{\mathbf{k}'}^{(I)}(\mathbf{s})$ for $\mathbf{k}' \in \Omega_1 \cup \Omega_2$, and integrate the product over the spatial domain. Then, the first term

 $-\vec{\boldsymbol{v}}_{\boldsymbol{s}}^T \triangledown \xi(t,\boldsymbol{s})$ on the RHS of (1) becomes:

$$-\vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T}\nabla\xi(t,\boldsymbol{s}) = \sum_{\boldsymbol{k}\in\Omega_{1}}\vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T}\tilde{\boldsymbol{k}}f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s})\alpha_{\boldsymbol{k}}^{(R)}(t) + 2\sum_{\boldsymbol{k}\in\Omega_{2}}\left\{\vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T}\tilde{\boldsymbol{k}}f_{\boldsymbol{k}}^{(I)}(\boldsymbol{s})\alpha_{\boldsymbol{k}}^{(R)}(t) - \vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T}\tilde{\boldsymbol{k}}f_{\boldsymbol{k}}^{(R)}(\boldsymbol{s})\alpha_{\boldsymbol{k}}^{(I)}(t)\right\}.$$
(58)

Hence, for any $\mathbf{k}' \in \Omega_1 \cup \Omega_2$, we have

$$-\int_{\mathbb{S}} \vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T} \nabla \xi(t, \boldsymbol{s}) f_{\boldsymbol{k}'}^{(R)}(\boldsymbol{s}) d\boldsymbol{s} = \sum_{\boldsymbol{k} \in \Omega_{1}} \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{1}(\boldsymbol{k}, \boldsymbol{k}') + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} \left\{ \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{1}(\boldsymbol{k}, \boldsymbol{k}') + \alpha_{\boldsymbol{k}}^{(I)}(t) \Psi_{2}(\boldsymbol{k}, \boldsymbol{k}') \right\}$$
(59)

$$-\int_{\mathbb{S}} \vec{\boldsymbol{v}}_{\boldsymbol{s}}^{T} \nabla \xi(t, \boldsymbol{s}) f_{\boldsymbol{k}'}^{(I)}(\boldsymbol{s}) d\boldsymbol{s} = \sum_{\boldsymbol{k} \in \Omega_{1}} \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{3}(\boldsymbol{k}, \boldsymbol{k}') + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} \left\{ \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{3}(\boldsymbol{k}, \boldsymbol{k}') + \alpha_{\boldsymbol{k}}^{(I)}(t) \Psi_{4}(\boldsymbol{k}, \boldsymbol{k}') \right\}$$

$$\tag{60}$$

The second term $\triangledown \cdot [\boldsymbol{D_s} \triangledown \xi(t, \boldsymbol{s})]$ on the RHS of (1) becomes:

$$\nabla \cdot [\boldsymbol{D}_{\boldsymbol{s}} \nabla \xi(t, \boldsymbol{s})] = \sum_{\boldsymbol{k} \in \Omega_{1}} \alpha_{\boldsymbol{k}}^{(R)}(t) (-\tilde{\boldsymbol{k}}^{T} \boldsymbol{D}_{\boldsymbol{s}} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)} - [\nabla \cdot \boldsymbol{D}_{\boldsymbol{s}}]^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(I)}) + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} \alpha_{\boldsymbol{k}}^{(R)}(t) (-\tilde{\boldsymbol{k}}^{T} \boldsymbol{D}_{\boldsymbol{s}} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)} - [\nabla \cdot \boldsymbol{D}_{\boldsymbol{s}}]^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(I)}) + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} \alpha_{\boldsymbol{k}}^{(I)}(t) (-\tilde{\boldsymbol{k}}^{T} \boldsymbol{D}_{\boldsymbol{s}} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(I)} - [\nabla \cdot \boldsymbol{D}_{\boldsymbol{s}}]^{T} \tilde{\boldsymbol{k}} f_{\boldsymbol{k}}^{(R)}).$$
(61)

Hence, for any $\mathbf{k}' \in \Omega_1 \cup \Omega_2$, we have

$$\int_{\mathbb{S}} \nabla \cdot [\boldsymbol{D}_{\boldsymbol{s}} \nabla \xi(t, \boldsymbol{s})] f_{\boldsymbol{k}'}^{(R)}(\boldsymbol{s}) d\boldsymbol{s} = \sum_{\boldsymbol{k} \in \Omega_{1}} \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{5}(\boldsymbol{k}, \boldsymbol{k}') + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} \left\{ \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{5}(\boldsymbol{k}, \boldsymbol{k}') + \alpha_{\boldsymbol{k}}^{(I)}(t) \Psi_{6}(\boldsymbol{k}, \boldsymbol{k}') \right\}$$

$$(62)$$

$$\int_{\mathbb{S}} \nabla \cdot [\boldsymbol{D}_{\boldsymbol{s}} \nabla \xi(t, \boldsymbol{s})] f_{\boldsymbol{k}'}^{(I)}(\boldsymbol{s}) d\boldsymbol{s} = \sum_{\boldsymbol{k} \in \Omega_{1}} \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{7}(\boldsymbol{k}, \boldsymbol{k}') + 2 \sum_{\boldsymbol{k} \in \Omega_{2}} \left\{ \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{7}(\boldsymbol{k}, \boldsymbol{k}') + \alpha_{\boldsymbol{k}}^{(I)}(t) \Psi_{8}(\boldsymbol{k}, \boldsymbol{k}') \right\}$$

$$(63)$$

The third term $-\zeta_{s}\xi(t, s)$ on the RHS of (1) becomes:

$$-\zeta_{s}\xi(t,s) = -\zeta_{s}\left(\sum_{k\in\Omega_{1}}\alpha_{k}^{(R)}(t)f_{k}^{(R)}(s) + 2\sum_{k\in\Omega_{2}}(\alpha_{k}^{(R)}(t)f_{k}^{(R)}(s) + \alpha_{k}^{(I)}(t)f_{k}^{(I)}(s))\right).$$
 (64)

Hence, for any $\mathbf{k}' \in \Omega_1 \cup \Omega_2$, we have

$$\int_{\mathbb{S}} -\zeta_{\boldsymbol{s}} \xi(t, \boldsymbol{s}) f_{\boldsymbol{k}'}^{(R)}(\boldsymbol{s}) d\boldsymbol{s} = \sum_{\boldsymbol{k} \in \Omega_1} \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_9(\boldsymbol{k}, \boldsymbol{k}') + 2 \sum_{\boldsymbol{k} \in \Omega_2} \left\{ \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_9(\boldsymbol{k}, \boldsymbol{k}') + \alpha_{\boldsymbol{k}}^{(I)}(t) \Psi_{10}(\boldsymbol{k}, \boldsymbol{k}') \right\}.$$
(65)

$$\int_{\mathbb{S}} -\zeta_{\boldsymbol{s}} \xi(t, \boldsymbol{s}) f_{\boldsymbol{k}'}^{(I)}(\boldsymbol{s}) d\boldsymbol{s} = \sum_{\boldsymbol{k} \in \Omega_1} \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{11}(\boldsymbol{k}, \boldsymbol{k}') + 2 \sum_{\boldsymbol{k} \in \Omega_2} \left\{ \alpha_{\boldsymbol{k}}^{(R)}(t) \Psi_{11}(\boldsymbol{k}, \boldsymbol{k}') + \alpha_{\boldsymbol{k}}^{(I)}(t) \Psi_{12}(\boldsymbol{k}, \boldsymbol{k}') \right\}$$
(66)

as was to be proved \blacksquare

D Proof of Proposition 4

For a spatially-varying but temporally-invariant convection-diffusion operator \mathcal{A} , the convection-diffusion operation $\mathcal{A}\tilde{\xi}(t, \boldsymbol{s})$ on the approximated process $\tilde{\xi}(t, \boldsymbol{s}) = \boldsymbol{f}^{T}(\boldsymbol{s})\boldsymbol{\alpha}(t)$ leads to

$$\boldsymbol{\alpha}(t+\Delta) = \exp(\boldsymbol{G}\Delta)\boldsymbol{\alpha}(t-1) \equiv \mathcal{G}\boldsymbol{\alpha}(t-1)$$
(67)

for discrete time steps with lag Δ . Note that, $\boldsymbol{\alpha}(t)$ is a vector of Fourier coefficients at frequencies $\boldsymbol{k}_1, \boldsymbol{k}_2, ..., \boldsymbol{k}_N$. Here, we explicitly write $\boldsymbol{\alpha}(t)$ as $\boldsymbol{\alpha}(t) = (\alpha_{\boldsymbol{k}_1}(t), \alpha_{\boldsymbol{k}_2}(t), ..., \alpha_{\boldsymbol{k}_N}(t))^T$.

Applying discrete inverse Fourier transform to both sides of (67), the left side becomes

$$\mathcal{F}^{-1}(\boldsymbol{\alpha}(t+\Delta)) = \sum_{j=1}^{N} \alpha_{\boldsymbol{k}_j}(t+\Delta) e^{i\boldsymbol{k}_j^T \boldsymbol{s}} = \tilde{\xi}(t+\Delta, \boldsymbol{s}), \tag{68}$$

while the right side of (67) yields:

$$\mathcal{F}^{-1}(\mathcal{G}\boldsymbol{\alpha}(t)) = \sum_{j=1}^{N} \sum_{j'=1}^{N} \mathcal{G}_{j,j'} \alpha_{\boldsymbol{k}_{j'}}(t) e^{i\boldsymbol{k}_{j}^{T}\boldsymbol{s}}$$
(69)

where $\mathcal{G}_{i,j}$ is the (j, j')th entry of the matrix \mathcal{G} .

Note that, $\boldsymbol{\alpha}_{\boldsymbol{k}_{j'}}(t) = N^{-1} \sum_{j=1}^{N} \tilde{\xi}(t, \boldsymbol{x}_i) e^{-\imath \boldsymbol{k}_{j'}^T \boldsymbol{x}_i}$ from the discrete Fourier transform. Hence, (69) can be written as

$$\sum_{j=1}^{N} \sum_{j'=1}^{N} \mathcal{G}_{j,j'} \alpha_{\boldsymbol{k}_{j'}}(t) e^{i\boldsymbol{k}_{j}^{T}\boldsymbol{s}} = \frac{1}{N} \sum_{i=1}^{N} \left[\sum_{j=1}^{N} \sum_{j'=1}^{N} \mathcal{G}_{j,j} e^{i\boldsymbol{k}_{j}\boldsymbol{s}-i\boldsymbol{k}_{j'}\boldsymbol{x}_{i}} \right] \tilde{\xi}(t,\boldsymbol{x}_{i})$$

$$= \frac{1}{N} \sum_{i=1}^{N} \omega_{\boldsymbol{s}}(\boldsymbol{x}_{i}) \tilde{\xi}(t,\boldsymbol{x}_{i})$$
(70)

and

$$\tilde{\xi}(t+\Delta, \boldsymbol{s}) = \frac{1}{N} \sum_{i=1}^{N} \omega_{\boldsymbol{s}}(\boldsymbol{x}_i) \tilde{\xi}(t, \boldsymbol{x}_i)$$
(71)

as was to be shown \blacksquare

E Discussions on the Computation Aspects

For spatially-varying convection, the computational bottle neck of the proposed model is the computation of a $N_1N_2 \times N_1N_2$ dense and non-symmetric matrix \boldsymbol{G} in (4). The evaluation of each component of \boldsymbol{G} requires the numerical integration of complex functions over the spatial domain. Note that, when the convection-diffusion does not vary in space and time, \boldsymbol{G} reduces to a diagonal matrix and the evaluation of each component of \boldsymbol{G} does not require numerical integration.

For example, our case study considers radar images with 200×200 pixels. Hence, \boldsymbol{G} is a $40,000 \times 40,000$ matrix, and the evaluation of each element of \boldsymbol{G} , i.e., $g_{i,j}$ in (4), requires a numerical integration of complex functions over the spatial domain. A total number of 1.6×10^9 numerical integrations are needed for evaluating the dense and non-symmetric matrix \boldsymbol{G} . Since \boldsymbol{G} contains unknown parameters, the statistical inference requires \boldsymbol{G} to be computed repeatedly, which is computationally expensive.

Figure 12: Computational scalability for evaluating the matrix G

Figure 12 provides the readers with some insights on the scalability of the computation of G as the dimension of G grows. In this figure, the first horizontal axis shows the cut-off frequency for low-pass filtering. For example, if the cut-off frequency equals 4, then, only those frequency components with their (absolute) angular wavenumber less than or equal 4 radians per unit distance are retained. The second horizontal axis shows the dimension of Gcorresponding to each chosen cut-off frequency. The vertical axis shows the relative growth of computational time. The computational time for a cut-off frequency of 2 radians per unit distance is used as the baseline for calculating the relatively growth in computational time.

Our code is written in R, and the evaluation of the components in G are performed in parallel using the **foreach** packages (i.e., parallel for loop). The code is implemented on a Dell workstation with 8 logical processors (Intel Xeon E3-1505M v6 3GHz), as well as the High Performance Computer (HPC) facilities with 16 nodes (Intel E5-2670 2.6GHz).

Because the statistical inference of the model parameters requires G to be repeatedly computed, we adopt a more practical two-step procedure in the case study in Section 5: 1) Step 1: estimate the unknown parameters (especially the wind field) using the low-pass filtered images by keeping only a relatively small number of low-frequency coefficients; 2) Step 2: perform Kalman Filter with known parameters. This two-step procedure is justified as follows: the most important parameter to be estimated is γ that determines the velocity field; see (43). The (macro-scale) velocity field can be well estimated from the dynamics/transition of the low-frequency terms which dominate the large-scale dynamics of the spatio-temporal process. Hence, in Step 1, only the low-frequencies coefficients are used (which maintains a low dimension of G) to estimate the unknown parameters. In our code, the evaluation of Gis approximately half a second for a cut-off frequency of 4 radians per unit distance. After the unknown parameters have been estimated, the Kalman Filter with known parameters is relatively fast.
