Multivariate Temporal Point Process Regression

Xiwei Tang and Lexin Li

Abstract

Point process modeling is gaining increasing attention, as point process type data are emerging in numerous scientific applications. In this article, motivated by a neuronal spike trains study, we propose a novel point process regression model, where both the response and the predictor can be a high-dimensional point process. We model the predictor effects through the conditional intensities using a set of basis transferring functions in a convolutional fashion. We organize the corresponding transferring coefficients in the form of a three-way tensor, then impose the low-rank, sparsity, and subgroup structures on this coefficient tensor. These structures help reduce the dimensionality, integrate information across different individual processes, and facilitate the interpretation. We develop a highly scalable optimization algorithm for parameter estimation. We derive the large sample error bound for the recovered coefficient tensor, and establish the subgroup identification consistency, while allowing the dimension of the multivariate point process to diverge. We demonstrate the efficacy of our method through both simulations and a cross-area neuronal spike trains analysis in a sensory cortex study.

Key Words: Conditional intensity function; Diverging dimension; Neuronal spike trains; Regularization; Temporal process; Tensor decomposition.

1 Introduction

Point process is drawing increasing attention, as data in the form of point process are emerging in a wide variety of scientific and business applications. Examples include forest ecology (Stoyan et al., 2000), spatial epidemiology (Diggle et al., 2010), social network modeling (Perry and Wolfe, 2013), neuronal activity modeling (Brown et al., 2004; Chen et al., 2019b), functional neuroimaging meta analysis (Kang et al., 2011, 2014), among others. In general, a point process is a collection of events, or points, randomly located in some domain space, e.g., a spatial domain or a time domain. Our motivation is a neuronal spike trains analysis in a sensory cortex study (Okun et al., 2015). A newly developed two-photon calcium imaging technique is now greatly facilitating neuroscience studies, by enabling simultaneously recording of the dynamic activities for a population of neurons while maintaining individual neuron resolution (Ji et al., 2016). In our study, there are 139 and 283 neurons imaged simultaneously from two areas of a rat's brain, the primary visual cortex area (V1) and the primary auditory cortex area (A1). In a visual activity, it is known that some locations of the primary visual cortex would respond to input from auditory and other sensory areas (Liang et al., 2013). One of the scientific goals of this study is to understand the association patterns and information transmissions between the neurons across A1 and V1, and to model potential excitation or inhibitory effects of neuron firings between the two areas.

In this article, we propose a new multivariate point process regression model to address this question, where both the response and the predictor can be a high-dimensional point process. We model the predictor effects through the conditional intensities using a set of basis transferring functions in a convolutional fashion. We organize the corresponding transferring coefficients in the form of a three-way tensor, then impose the low-rank, sparsity, and subgroup structures. Both low-rank and sparsity are commonly used low-dimensional structures in high-dimensional data analysis, and are scientifically plausible in neuroscience and many other applications (Zhou et al., 2013a; Chen et al., 2019a; Zhang and Han, 2019; Bacry et al., 2020). Subgroup is another frequently used structure in plenty of applications, and it corresponds to ensemble neural activities in neuroscience (Okun et al., 2015). Together these structures effectively reduce the number of free parameters, and greatly facilitate the model interpretation. Under the proposed model, we develop a highly scalable alternating direction method of multipliers algorithm for parameter estimation. We establish the asymptotic properties of the penalized maximum likelihood estimator while allowing the dimensions of both the response and the predictor process to diverge. We also comment that, although motivated by a neuroscience problem, our method is equally applicable to numerous

other point process applications, e.g., the social infection network learning (Zhou et al., 2013b).

There have been a large number of models targeting a spatial point process, where its local intensity is usually assumed to depend on some deterministic features or some location-relevant random variables (see, e.g., Guan, 2008; Guan et al., 2015; Kang et al., 2014; Deng et al., 2017). We instead aim at a temporal point process, which is usually evolutionary in nature, in that the occurrence of a future event depends on the historical realizations of the process. This leads to a different set of model assumptions and modeling techniques. Moreover, most classical inhomogeneous point process solutions target a univariate or bivariate process along with a limited number of predictors (Diggle et al., 2010; Waagepetersen and Guan, 2009). We instead target high-dimensional response and predictor processes, and we allow the dimension of both processes to diverge. This has introduced new challenges in both modeling and theoretical analysis.

There have also been a family of models targeting a temporal point process, all of which are built on a self-exciting process called the Hawkes process (Hawkes, 1971). A Hawkes process assumes that a future event is triggered by its own past events, and is widely used in neuronal spike trains analysis as well. In recent years, there have been a number of point process models extending the Hawkes process. Our proposal is related to but also clearly distinctive from the existing models in multiple ways. First of all, our model extends the classical Hawkes process, by simultaneously incorporating nonlinear and inhomogeneous intensities, multiple basis functions, diverging point process dimensions, and additional structures on the transferring coefficients. On the other hand, our model is more general, in that it allows a wide class of stochastic processes to be predictors, and can be applied to the scenarios where the Hawkes process is applicable, but not vice versa. We give some examples in Section 2.2. Second, Zhou et al. (2013b) introduced low-rank and sparsity structures in a multivariate Hawkes model. Bacry et al. (2020) studied the theoretical properties of the model, while potentially allowing the point process dimension to diverge. Our proposal employs similar low-dimensional structures and explicitly studies the diverging dimension. However, there are numerous fundamental differences. Zhou et al. (2013b); Bacry et al. (2020) both imposed the linear link function and the stationary assumption, whereas we consider a general and potentially nonlinear link, and do not require the process to be stationary. In addition, Zhou et al. (2013b); Bacry et al. (2020) organized the transferring coefficients in a matrix form and placed a low-rank structure on the coefficient matrix, whereas we organize the transferring coefficients in a tensor form and employ a low-rank tensor decomposition. Tensor decomposition is considerably different from matrix decomposition (Kolda and Bader, 2009), and naively transforming a tensor to a matrix may lose information. More importantly, the estimation error bound obtained by Bacry et al. (2020) is to increase as the point process dimension diverges, and as such the estimator is to suffer from the increasing dimension. By contrast, in Section 4.2, we show that the diverging dimension is to benefit our penalized maximum likelihood estimator, and leads to a faster convergence rate on the asymptotic concentration. Third, Hansen et al. (2015) considered an intensity-based model for multivariate Hawkes process with a fixed dimension, and adopted the least-squares estimation and ℓ_1 regularization. However, the key difference is that Hansen et al. (2015) modeled each individual point process separately, while we model multiple processes jointly. More specifically, even though Hansen et al. (2015) targeted a multivariate point process, their loss function was completely separable. As such, they essentially modeled each individual point process one at a time. By contrast, we model multiple response point processes in a joint fashion, in that we integrate and borrow information across different response processes. This is achieved through both the tensor latent factors that are shared across all intensity functions, as well as the subgrouping structure on the transferring coefficients that encourage information sharing among similar individual processes. Such a joint modeling strategy essentially leads to the improved estimation bound when the number of response processes increases. Finally, Bacry and Muzy (2016) and Chen et al. (2019b) studied some multivariate Hawkes process models using moment-based statistics, while we focus on modeling the conditional intensity function. In Section 2.2, we discuss in more detail why the intensity-based approach is more suitable than the momentbased approach in our setting.

The rest of the article is organized as follows. Section 2 introduces our proposed multivariate temporal point process regression model. Section 3 develops the estimation algorithm, and Section 4 derives the theoretical properties. Section 5 presents the simulations, and Section 6 illustrates with a neuronal spike trains data analysis. All proofs are relegated to the Supplementary Appendix.

2 Model

2.1 Background

We begin with a brief review of temporal point process, and we refer to Daley and Vere-Jones (2007) for more details. Specifically, a temporal point process is a stochastic counting process defined on the positive half of the real line \mathbb{R}^+ , and taking non-negative integer values. For a univariate process X(t), let $t_1, t_2, \ldots \in \mathbb{R}^+$ denote the event times, under which $X(A) = \sum_{l=1} \mathbf{1}_{[t_l \in A]}$ for any $A \in \mathcal{B}(\mathbb{R}^+)$, and $\mathcal{B}(\mathbb{R}^+)$ denotes the Borel σ -algebra of \mathbb{R}^+ . Define its mean intensity func-

tion as $\Lambda(t) = \lim_{dt\to 0} \mathbb{E}[dX(t)]/dt$, where dX(t) = X([t,t+dt)), and dt is an arbitrary small increment of time. A temporal point process is homogeneous if its mean intensity is a constant, and is inhomogeneous otherwise. If $\Lambda(t)$ is also a stochastic process, then it is a doubly stochastic process; e.g., a Cox process. A temporal point process is usually assumed to be orderly; i.e., $\Pr(dX(t) > 1) = o(dt)$, which implies that $\Lambda(t) = \Pr(dX(t) = 1)$. In addition, a point process X(t) is stationary, if the distribution of dX(t) only depends on the length of dt but not the location t on the time line. It is straightforward to generalize the notion of a univariate point process to a multivariate point process, i.e., $X(t) = (X_1(t), \dots, X_p(t))^\mathsf{T}$.

Moment statistics are widely used in point process modeling, especially for a stationary process (Guan, 2008, 2011; Chen et al., 2019b). Considering a p-dimensional stationary point process X(t), define its first-order moment statistic, i.e., the mean intensity, and its second-order statistic, i.e., the covariance, as,

$$\Lambda_i^x = \mathbb{E}\{dX_i(t)\}/dt, \quad i = 1, \dots, p,$$

$$V_{ij}^x(\tau) = \mathbb{E}\{dX_i(t)dX_j(t-\tau)\}/\{dtd(t-\tau)\} - \Lambda_i\Lambda_j - \delta_{ij}(\tau)\Lambda_i, \quad i, j = 1, \dots, p,$$

respectively, where $\delta_{ij}(\tau)=0$ if $i\neq j$, and $\delta_{ij}(\tau)=\delta(\tau)$ if i=j, and $\delta(\cdot)$ denotes the Dirac delta function satisfying that $\delta(x)=0$ for $x\neq 0$ and $\int_{-\infty}^{+\infty}\delta(x)dx=1$. Write $\mathbf{\Lambda}^x=(\Lambda_1^x,\ldots,\Lambda_p^x)^{\mathsf{T}}\in\mathbb{R}^p$, and $\mathbf{V}^{xx}(\cdot)=\left(V_{ij}^x(\cdot)\right):\mathbb{R}\mapsto\mathbb{R}^{p\times p}$. Analogously, consider another m-dimensional stationary point process $\mathbf{Y}(t)$, with the mean intensity $\mathbf{\Lambda}^y=(\Lambda_1^y,\ldots,\Lambda_m^y)^{\mathsf{T}}\in\mathbb{R}^m$, and the covariance $\mathbf{V}^{yy}(\cdot)=\left(V_{ij}^y(\cdot)\right):\mathbb{R}\mapsto\mathbb{R}^{m\times m}$. The cross-covariance between $X_j(t)$ and $Y_i(t)$ is defined as,

$$C_{ji}^{xy}(\tau) = \mathbb{E}\{dX_j(t)dY_i(t-\tau)\}/\{dtd(t-\tau)\} - \Lambda_j^x \Lambda_i^y, \quad i = 1, \dots, m, j = 1, \dots, p.$$

Write
$$C^{xy}(\cdot) = \left(C^{xy}_{ji}(\cdot)\right) : \mathbb{R} \mapsto \mathbb{R}^{p \times m}$$
, and $C^{yx}(\cdot) = \left(C^{yx}_{ij}(\cdot)\right) : \mathbb{R} \mapsto \mathbb{R}^{m \times p}$.

Conditional intensity function is another extensively used tool for modeling both spatial and temporal point process with additional covariates. For our proposed multivariate point process regression, we mainly target the conditional intensity function, as we detail in the next section.

2.2 Multivariate point process regression

We consider a temporal regression model with a p-dimensional predictor process $\mathbf{X}(t)$ and an m-dimensional response process $\mathbf{Y}(t)$. Letting \mathcal{H}_t denote the σ -algebra generated by $\{\mathbf{X}(t), \mathbf{Y}(t)\}$, then the \mathcal{H}_t -predictable intensity function $\lambda_i^y(t)$ of the ith response process $Y_i(t)$ is defined as,

$$\lambda_i^y(t)dt = \Pr\left\{dY_i(t) = 1 | \mathcal{H}_t\right\}, \quad i = 1, \dots, m.$$

We assume this conditional intensity function takes the form,

$$\lambda_i^y(t) = \phi \left\{ \mu_i + \sum_{j=1}^p (\omega_{ij} * dX_j)(t) \right\}, \quad i = 1, \dots, m,$$
 (1)

where $\phi(\cdot)$ is a link function that is possibly nonlinear, e.g., a rectifier function $\phi(x) = \max(0, x)$, or a sigmoid function $\phi(x) = e^x/(1 + e^x)$, μ_i is the background intensity, and $\omega_{ij}(\cdot) : \mathbb{R}^+ \to \mathbb{R}$ is the transferring function, $i = 1, \ldots, m, j = 1, \ldots, p$. Write $\boldsymbol{\mu} = (\mu_1, \ldots, \mu_m)^\mathsf{T} \in \mathbb{R}^m$, and $\boldsymbol{\omega} = (\omega_{ij}(\cdot)) \in \mathbb{R}^{m \times p}$. To account for potential evolution over time, we further assume that the transferring function $\omega_{ij}(\cdot)$ models the historical information of the predictor process $\boldsymbol{X}(t)$ in a convolutional fashion, in that,

$$(\omega_{ij} * dX_j)(t) = \int_0^t \omega_{ij}(\Delta) dX_j(t - \Delta).$$
 (2)

Similar formulation such as (2) has been commonly used in the temporal point process literature (e.g., Hawkes, 1971; Zhou et al., 2013b). We also note that, (1) and (2) together cover a fairly general class of models. We do no require a linear link function, nor the stationary condition. We do not enforce $\omega_{ij}(\cdot)$ to be non-negative, as typically in the classical Hawkes process model, and therefore allow both "exciting" and "inhibiting" effects among different processes. In addition, we allow the predictor process X(t) to take a general form. The convolution in (2) actually works for both a stochastic predictor process and a deterministic predictor process, corresponding to a stochastic integral or a Stieltjes integral, respectively.

We next outline a number of examples covered under our proposed model framework.

Example 1. Let $X_j(t)$, j = 1, ..., p, be a deterministic function on $[0, \infty)$, and $\mathbf{Y}(t)$ turns to be a multivariate inhomogeneous Poisson process with the deterministic mean intensity function $\lambda_i^y(t)$, i = 1, ..., p. In a neuronal activity study, $\mathbf{X}(t)$ may represent the designed stimulus signal.

Example 2. Let $X_j(t)$, j = 1, ..., p, be a stochastic point process, and $\mathbf{Y}(t)$ turns to be a multivariate Cox process or a doubly-stochastic process. If the transferring function $\omega_{ij}(x)$ takes the form such as a Dirac delta function $\delta(x-t)$, then the conditional intensity $\lambda_i^y(t)$ only depends on the value of $\mathbf{X}(t)$ at point t. Consequently, our model can also be applied to non-temporal point processes, e.g., a multivariate spatial point process.

Example 3. Let X(t) = Y(t) be the same stochastic point process. Then our proposed model includes the Hawkes process as a special case. The classical Hawkes process model only considers self-exciting effects, i.e., $\omega_{ij}(\cdot)$ has to be non-negative. Moreover, it usually assumes the process is

stationary, which requires additional conditions on $\omega_{ij}(\cdot)$, e.g., the spectral radius is smaller than one (Brémaud and Massoulié, 1996). We do not impose such constraints.

Example 4. For our motivating neuronal spike trains example, let $N_{V1}(t)$, $N_{A1}(t)$ denote the multivariate point process for the neuron firing activities on the layers V1 and A1, respectively. If we expect that there are only directed connections between the neurons from A1 to V1 (Liang et al., 2013), then we can set $\mathbf{Y}(t) = \mathbf{N}_{V1}(t)$, and $\mathbf{X}(t) = \mathbf{N}_{A1}(t)$. Meanwhile, if we also expect potential connections between the neurons within the same layer of V1, then we can set $\mathbf{Y}(t) = \mathbf{N}_{V1}(t)$, and $\mathbf{X}(t) = (\mathbf{N}_{V1}(t), \mathbf{N}_{A1}(t))$, which takes the history of $\mathbf{N}_{V1}(t)$ into account as well. Consequently, the transferring coefficient $\boldsymbol{\omega}_{A1}$ of $\mathbf{N}_{A1}(t)$ in this model captures the association between $\mathbf{N}_{V1}(t)$ and $\mathbf{N}_{A1}(t)$ after controlling the cross-connections within $\mathbf{N}_{V1}(t)$ itself.

In our temporal point process modeling, we mainly target the conditional intensity function, instead of the moment statistics, for several reasons. To illustrate, we consider a special case of our model (1), which takes a linear link function, i.e.,

$$\lambda_i^y(t) = \mu_i + \sum_{j=1}^p \{\omega_{ij} * dX_j\}(t), \quad i = 1, \dots, m.$$
 (3)

We next summarize the first and second-order statistics under this special case.

Proposition 1. Consider a special case of (1), such that $\mathbf{X}(t)$ and $\mathbf{Y}(t)$ satisfy the linear relation (3), and both are stationary. Then the corresponding moment statistics are of the form,

$$\Lambda^{y} = \mu + \left\{ \int_{0}^{+\infty} \omega(\Delta) d\Delta \right\} \Lambda^{x}, \quad C^{yx}(\tau) = \omega(\tau) Diag(\Lambda^{x}) + \omega * V^{xx}(\tau), \quad \tau \ge 0
V^{yy}(\tau) = \omega * C^{xy}(\tau), \quad \tau > 0, \quad V^{yy}(0) = \omega * \{V^{xx}(\cdot) + Diag(\Lambda^{x})\} * \omega,$$
(4)

where $\boldsymbol{\omega} * \boldsymbol{C}^{xy}(\tau) = \omega_{ij}(\cdot) * C_{ji}^{xy}(\tau)$, and $f * g(t) = \int f(\Delta)g(t-\Delta)d\Delta$ denotes the convolution of two univariate functions f and g, and $\boldsymbol{\omega} * \{\boldsymbol{V}^{xx}(\cdot) + Diag(\boldsymbol{\Lambda}^x)\} * \boldsymbol{\omega} = \int_0^{+\infty} \int_0^{+\infty} \boldsymbol{\omega}(\Delta) \{Diag(\boldsymbol{\Lambda}^x) \delta(\Delta' - \Delta) + \boldsymbol{V}^{xx}(\Delta' - \Delta)\} \boldsymbol{\omega}^{\mathsf{T}}(\Delta') d\Delta d\Delta'$.

The equations in (4) belong to a class of integral equations for the Wiener-Hopf system with respect to ω . In principle, one can estimate the transferring function by solving the above equations and plugging in the estimated first and second-order statistics of X(t) and Y(t). However, this strategy is not suitable for our model, because the moment-based estimation can be challenging when the dimension of the point process is high and diverging. Besides, the relation between the moment statistics and the transferring function in our model is much more complicated compared to a

Hawkes process. For the latter, the second-order statistics full capture the associations between the marginal processes. In our model, however, the second-order statistics V^{yy} and C^{yx} also depend on the cross-covariance structure of the predictor process X(t). Finally, nearly all moment-based estimation methods require the stationary condition, which can be restrictive in practice. For these reasons, we choose to adopt an intensity-based modeling approach.

2.3 Low-rank structure

In our model, the transferring function ω that fully captures the cross-process connection pattern is of primary interest. Adopting a common strategy in point process modeling, we assume that $\omega_{ij}(t)$ takes the form of a linear combination of a set of basis functions, $g^{(k)}(t), k = 1, ..., K$, in that,

$$\omega_{ij}(t) = \sum_{k=1}^{K} \beta_{ij}^{k} \cdot g^{(k)}(t), \quad i = 1, \dots, m, \ j = 1, \dots, p,$$
(5)

where each $g^{(k)}(t)$ is a non-negative basis function on $[0, \infty)$, K is the number of basis functions, and β_{ij}^k 's can take positive and negative values. The choice of basis functions mostly relies on the scientific knowledge to account for specific coevolutionary effects (Hansen et al., 2015). In neuronal spike trains study, common basis functions include the exponential function, $g(t) = a \exp(-at)$, a > 0 (Zhou et al., 2013b), the logarithmic decay function, $g(t) = \log(1 + T - t)$, for the process defined on [0, T] (Luo et al., 2016), and the piecewise constant function, $g_l(t) = a_l \mathbf{1}(t \in \mathcal{T}_l)$, where $\{\mathcal{T}_l\}_{l=1}^L$ form a partition of $[0, +\infty]$ and $\{a_l\}_{l=1}^L$ are some non-negative constants (Wang et al., 2016). One may also use a mix of different types of basis functions.

Given the basis expansion in (5), the conditional intensity model in (1) can be rewritten as,

$$\lambda_i^y(t) = \phi \left[\mu_i + \sum_{j=1}^p \sum_{k=1}^K \beta_{ij}^k \cdot \{g^{(k)} * dX_j\}(t) \right], \quad i = 1, \dots, m.$$
 (6)

We then collect the transferring coefficients into a three-way tensor $\mathcal{B} \in \mathbb{R}^{m \times p \times K}$, with the entry β_{ij}^k , $i=1,\ldots,m,\ j=1,\ldots,p,\ k=1,\ldots,K$. The conditional intensity function is now fully characterized by the background intensity vector $\boldsymbol{\mu}$ and the transferring coefficient tensor $\boldsymbol{\mathcal{B}}$.

We can estimate the model through a likelihood-based approach, where the joint log-likelihood function is of the form,

$$\mathcal{L}(\boldsymbol{\mu}, \boldsymbol{\mathcal{B}}|\boldsymbol{Y}(t), \boldsymbol{X}(t)) = \frac{1}{T} \sum_{i=1}^{m} L_{i}(\boldsymbol{\mu}, \boldsymbol{\mathcal{B}}|Y_{i}(t), \boldsymbol{X}(t))$$

$$= \frac{1}{T} \sum_{i=1}^{m} \int_{0}^{T} \left[\log \left\{ \lambda_{i}^{y}(t; \boldsymbol{\mathcal{B}}, \boldsymbol{X}(t)) \right\} dY_{i}(t) - \lambda_{i}^{y}(t; \boldsymbol{\mathcal{B}}, \boldsymbol{X}(t)) dt \right].$$
(7)

In the following discussion, we drop Y(t), X(t) and \mathcal{B} in $\mathcal{L}(\mu, \mathcal{B})$ and $\lambda_i^y(t)$ for notational simplicity whenever there is no confusion.

Next, we impose that \mathcal{B} admits a low-rank CANDECOMP/PARAFAC (CP) structure, in that,

$$\mathcal{B} = \sum_{r=1}^{R} \nu_r \boldsymbol{b}_r^y \circ \boldsymbol{b}_r^x \circ \boldsymbol{b}_r^c, \tag{8}$$

where R is the tensor rank, $m{b}_r^y \in \mathbb{R}^m$, $m{b}_r^x \in \mathbb{R}^p$ and $m{b}_r^c \in \mathbb{R}^K$ are the normalized vectors corresponding to the modes of the response process, the predictor process, and the convolutional basis functions, respectively, ν_r 's are the normalization weights, and " \circ " is the outer product. For notational convenience, we represent the decomposition (8) by a shorthand, $\mathcal{B} = [\nu; B^y, B^x, B^c]$, where $m{B}^y = [m{b}_1^y \ \dots m{b}_R^y] \in \mathbb{R}^{m \times R}, \, m{B}^x = [m{b}_1^x \ \dots m{b}_R^x] \in \mathbb{R}^{p \times R}, \, m{B}^c = [m{b}_1^c \ \dots m{b}_R^c] \in \mathbb{R}^{K \times R}$, and $\boldsymbol{\nu} = (\nu_1, \dots, \nu_R)^\mathsf{T} \in \mathbb{R}^R$. See Kolda and Bader (2009) for a review of tensor and its decomposition. The low-rank decomposition (8) has been widely adopted in recent years in imaging-based tensor regressions (Zhou et al., 2013a; Sun and Li, 2017; Chen et al., 2019a). In the context of point process modeling, Zhou et al. (2013b); Bacry et al. (2020) also adopted a low-rank structure in a linear Hawkes model, yet on a matrix form of their transferring coefficients. By contrast, we target a nonlinear, non-stationary, general temporal point process, and consider a low-rank structure on a coefficient tensor. Even though tensor is a conceptual generalization of matrix, tensor decomposition and matrix decomposition are considerably different (Kolda and Bader, 2009). Naively transforming a tensor to a matrix may lose information. We also briefly remark that, there are easy-to-check sufficient conditions to ensure the decomposition in (8) is unique up to permutations (Sidiropoulos and Bro, 2000).

Imposing the low-rank structure like (8) in our point process regression has several advantages. First, it substantially reduces the number of free parameters in the transferring coefficient tensor \mathcal{B} , from mpK to R(m+p+K). In our example, if we set $\mathbf{Y}(t) = \mathbf{N}_{V1}(t)$, and $\mathbf{X}(t) = \mathbf{N}_{A1}(t)$, the dimensions of the response and predictor processes are m=139 and p=283, respectively. If we choose K=3 basis functions, and choose the rank R=4, then the number of free parameters in \mathcal{B} reduces from 118,011 to 1,700. Second, and perhaps more importantly, it allows us to model the multivariate point process in a joint fashion. Existing approaches such as Hansen et al. (2015) model each response process $Y_i(t)$ separately, since their loss function is separable with respect to the individual intensity function $\lambda_i^y(t)$, each of which depends on a separate set of parameters \mathcal{B}_i . By contrast, our model with (8) suggests that \mathcal{B} relies on some underlying latent and interrelated factors, \mathcal{B}^y , \mathcal{B}^x and \mathcal{B}^c . In the context of neuronal spike trains modeling, it im-

plies that a particular predictor neuron in X(t) exercises similar influence on multiple response neurons in Y(t), or a particular response neuron in Y(t) enjoys similar influence from multiple predictor neurons in X(t). Unlike the separate modeling strategy, the latent factors B^x and B^c are commonly shared by all intensity functions $\lambda_i(t)$'s, and thus information across different response processes $Y_i(t)$'s is integrated. Such an integration leads to an improved coefficient estimator, as we show asymptotically in Section 4.2.

2.4 Additional structure pursuit: sparsity and subgrouping

To better accommodate scientific knowledge, improve the interpretation, and further reduce the number of free parameters, we consider some additional structure pursuit.

The first structure we pursue is sparsity, in that only a subset of response processes are affected by a subset of predictor processes. This sparsity structure simplifies the model interpretation, further reduces the number of parameters, and is scientifically plausible. In multivariate Hawkes process modeling, the sparsity on transferring functions has been widely employed (Hansen et al., 2015; Bacry et al., 2020). Specifically, we impose a group ℓ_1 penalty (Yuan and Lin, 2006) on the coefficient tensor \mathcal{B} ,

$$P_s(\mathbf{B}; \tau_s) = \tau_s \sum_{i=1}^m \sum_{j=1}^p \|\mathbf{B}[i, j, \cdot]\|_2,$$
 (9)

where $\mathcal{B}[i,j,\cdot] \in \mathbb{R}^R$ is a vector of \mathcal{B} with the first two indices fixed and the third index varying, which corresponds to the associations between $Y_i(t)$ and $X_j(t)$ under all basis functions, τ_s is the sparsity tuning parameter, and $\|\cdot\|_2$ is the ℓ_2 norm.

The second structure we pursue is subgrouping. In a neuronal spike trains study, subsets of neurons are expected to share similar patterns in neuronal firing activities, and such clustering patterns are usually of great scientific interest (Kim et al., 2011). Similar phenomenon is commonly observed in numerous other applications too. Such patterns are reflected by the underlying clustering structure in the transferring function ω . To capture this structure, we embed clustering pursuit into the proposed tensor decomposition. In principle, we can pursue clustering in the response process, or the predictor process, or both. For our motivating example, there is evidence of neuron clustering in the primary visual cortex V1, i.e., the response process (Liang et al., 2013). As such, we introduce a grouping penalty on the decomposed factors of the response mode B^y , so to encourage clustering of the response neurons. Specifically, we impose a pairwise fusion penalty,

$$P_f(\boldsymbol{B}^y; \tau_f) = \sum_{i < i'} f_{\kappa} (\|\boldsymbol{B}^y[i, \cdot] - \boldsymbol{B}^y[i', \cdot]\|_2, \tau_f), \qquad (10)$$

where $\mathbf{B}^y[i,\cdot] \in \mathbb{R}^R$ is the row vector of \mathbf{B}^y , τ_f is the fusion parameter, and the penalty function $f_\kappa(t,\tau) = \tau \int_0^t \{1 - x/(\tau\kappa)\}_+ dx$, with κ being a thresholding parameter (Zhang, 2010). This penalty function is to help reduce the estimation bias, as it only groups the individual predictors with similar effects on the responses through a non-convex fusion penalty (Zhu et al., 2019).

3 Estimation

3.1 ADMM optimization

We develop a highly scalable ADMM type optimization algorithm (Boyd et al., 2011) to estimate the parameters in our proposed model. Consider the realizations of the predictor and response processes $\boldsymbol{X}(t)$ and $\boldsymbol{Y}(t)$ on a time interval [0,T]. Let $t_1^i < t_2^i < \cdots < t_{n_i}^i$ denote the time points of the n_i events of the response process $Y_i(t)$ that are observed on [0,T], $i=1,\ldots,m$. Given the set of basis functions $\{g^{(k)}(\cdot)\}_{k=1}^K$, the log-likelihood function in our model can be written as

$$\mathcal{L}(\boldsymbol{\mu}, \boldsymbol{\mathcal{B}}) = \frac{1}{T} \sum_{i=1}^{m} \left(-\int_{0}^{T} \phi \left\{ \mu_{i} + \langle \boldsymbol{G}(t), \boldsymbol{\mathcal{B}}[i, \cdot, \cdot] \rangle \right\} dt + \sum_{l=1}^{n_{i}} \log \left[\phi \left\{ \mu_{i} + \langle \boldsymbol{G}(t_{l}^{i}), \boldsymbol{\mathcal{B}}[i, \cdot, \cdot] \rangle \right\} \right] \right),$$

where $G(t) = (G_{j,k}(t)) \in \mathbb{R}^{p \times K}$, $G_{j,k}(t) = \{g^{(k)} * dX_j\}(t)$, $\mathcal{B}[i,\cdot,\cdot] \in \mathbb{R}^{p \times K}$ is a matrix from \mathcal{B} with the first index fixed and the other two indices varying, and $\langle \cdot, \cdot \rangle$ denotes the inner product.

Incorporating the low-rank structure (8) and the two regularization structures (9) and (10), we aim at the following optimization problem,

$$\min_{\boldsymbol{\mu}, \boldsymbol{\nu}, \boldsymbol{B}^{y}, \boldsymbol{B}^{x}, \boldsymbol{B}^{c}} \left\{ -\mathcal{L}(\boldsymbol{\mu}, \llbracket \boldsymbol{\nu}; \boldsymbol{B}^{y}, \boldsymbol{B}^{x}, \boldsymbol{B}^{c} \rrbracket) + \tau_{s} \sum_{i=1}^{m} \sum_{j=1}^{p} \left\| \llbracket \boldsymbol{\nu}; \boldsymbol{B}^{y}, \boldsymbol{B}^{x}, \boldsymbol{B}^{c} \rrbracket[i, j, \cdot] \right\|_{2} + \sum_{i < i'} f_{\kappa} \left(\left\| \boldsymbol{B}^{y}[i, \cdot] - \boldsymbol{B}^{y}[i', \cdot] \right\|_{2}, \tau_{f} \right) \right\}. \tag{11}$$

The optimization in (11) is challenging in several ways. It involves a tensor decomposition embedded in a complicated log-likelihood function with summation of integrals and a possibly nonlinear link function ϕ . In addition, the sparsity penalty in (9) is non-differentiable, while the fusion penalty in (10) is non-convex. Moreover, (10) involves the differences of parameters, rendering those parameters inseparable in optimization. To overcome those challenges, and to achieve computational scalability, we develop an ADMM algorithm for the optimization in (11).

Specifically, we introduce three sets of auxiliary variables. The first set is $\mathcal{A} \in \mathbb{R}^{m \times p \times K}$ that targets the low-rank structure (8) such that $\mathcal{A} = \mathcal{B} = \llbracket \boldsymbol{\nu}; \boldsymbol{B}^y, \boldsymbol{B}^x, \boldsymbol{B}^c \rrbracket$. The second set is $\Psi \in \mathbb{R}^{m \times p \times K}$ with $\Psi[i,j,\cdot] = \psi_{ij} \in \mathbb{R}^K$ that targets the sparsity structure (9) such that

 $\psi_{ij} = \mathcal{B}[i,j,\cdot], 1 \leq i \leq m, 1 \leq j \leq p$. The third set is $\Gamma \in \mathbb{R}^{m(m-1)/2 \times R}$ that stacks $\gamma_{ii'} \in \mathbb{R}^R$ together and targets the subgroup structure (10) such that $\gamma_{ii'} = \mathbf{B}^y[i,\cdot] - \mathbf{B}^y[i',\cdot], 1 \leq i < i' \leq m$. We then rewrite (11) in its equivalent form,

$$\min_{\boldsymbol{\mu}, \boldsymbol{\nu}, \boldsymbol{B}^{y}, \boldsymbol{B}^{x}, \boldsymbol{B}^{c}, \boldsymbol{\mathcal{A}}, \boldsymbol{\Psi}, \boldsymbol{\Gamma}} \left\{ -\mathcal{L}(\boldsymbol{\mu}, \boldsymbol{\mathcal{A}}) + \tau_{s} \sum_{i=1}^{m} \sum_{j=1}^{p} \|\boldsymbol{\psi}_{ij}\|_{2} + \sum_{j < j'} f_{\kappa} (\|\boldsymbol{\gamma}_{ii'}\|_{2}, \tau_{f}) \right\}$$
subject to $\boldsymbol{\mathcal{A}} = [\![\boldsymbol{\nu}; \boldsymbol{B}^{y}, \boldsymbol{B}^{x}, \boldsymbol{B}^{c}]\!], \quad \boldsymbol{\Psi} = \boldsymbol{\mathcal{B}}, \quad \boldsymbol{\Gamma} = \boldsymbol{D}_{m} \boldsymbol{B}^{y},$

where $D_m \in \mathbb{R}^{m(m-1)/2 \times m}$ that stacks $d_{ii'} \in \mathbb{R}^m$ together, with $d_{ii'} = e_i - e_{i'}$, $e_i \in \mathbb{R}^m$ has one on the *i*th position and zero elsewhere, $1 \le i < i' \le m$. Note that the second constraint $\Psi = \mathcal{B}$ can also be written as $\Psi = \mathcal{A}$ due to the first constraint. To solve (12), we minimize the following augmented Lagrangian objective function,

$$\begin{split} &-\mathcal{L}(\boldsymbol{\mathcal{A}},\ \boldsymbol{\mu}) + \tau_s \sum_{i,j} \|\boldsymbol{\psi}_{ij}\|_2 + \sum_{j < j'} f_{\kappa}(\|\boldsymbol{\gamma}_{ii'}\|_2, \tau_f) \\ &+ \langle \boldsymbol{\mathcal{W}}_1, \boldsymbol{\mathcal{A}} - [\![\boldsymbol{\nu}; \boldsymbol{B}^y, \boldsymbol{B}^x, \boldsymbol{B}^c]\!] \rangle + \langle \boldsymbol{\mathcal{W}}_2, \boldsymbol{\Psi} - \boldsymbol{\mathcal{A}} \rangle + \langle \boldsymbol{W}_3, \boldsymbol{\Gamma} - \boldsymbol{D}_m \boldsymbol{B}^y \rangle \\ &+ \frac{\rho}{2} \left(\|\boldsymbol{\mathcal{A}} - [\![\boldsymbol{\nu}; \boldsymbol{B}^y, \boldsymbol{B}^x, \boldsymbol{B}^c]\!] \|_F^2 + \|\boldsymbol{\Psi} - \boldsymbol{\mathcal{A}} \|_F^2 + \|\boldsymbol{\Gamma} - \boldsymbol{D}_m \boldsymbol{B}^y \|_F^2 \right), \end{split}$$

where $\mathcal{W}_1, \mathcal{W}_2 \in \mathbb{R}^{m \times p \times K}$ and $\mathcal{W}_3 \in \mathbb{R}^{m(m-1)/2 \times m}$ are the corresponding Lagrangian multipliers, $\rho > 0$ is a fixed augmented parameter, and $\|\cdot\|_F$ denotes the Frobenius norm.

Next we update the blocks of parameters, $\boldsymbol{\mu}$, $\boldsymbol{\mathcal{A}}$, $\boldsymbol{\nu}$, \boldsymbol{B}^y , \boldsymbol{B}^c , $\boldsymbol{\Psi}$, $\boldsymbol{\Gamma}$, and the Lagrangian multipliers $\boldsymbol{\mathcal{W}}_1, \boldsymbol{\mathcal{W}}_2, \boldsymbol{W}_3$ in an alternating fashion. That is, given the estimates at the sth iteration, $\boldsymbol{\mathcal{A}}^{(s)}, \boldsymbol{\mathcal{B}}^{(s)} = [\![\{\boldsymbol{\nu}\}^{(s)}; \{\boldsymbol{B}^y\}^{(s)}, \{\boldsymbol{B}^x\}^{(s)}, \{\boldsymbol{B}^c\}^{(s)}]\!], \boldsymbol{\Psi}^{(s)}, \boldsymbol{\Gamma}^{(s)}, \boldsymbol{\mathcal{W}}_1^{(s)}, \boldsymbol{\mathcal{W}}_2^{(s)}, \boldsymbol{\mathcal{W}}_3^{(s)}$, we update:

$$\boldsymbol{\mu}^{(s+1)}, \boldsymbol{\mathcal{A}}^{(s+1)} = \underset{\boldsymbol{\mu}, \boldsymbol{\mathcal{A}}}{\operatorname{argmin}} - \mathcal{L}(\boldsymbol{\mathcal{A}}, \ \boldsymbol{\mu}) + \frac{\rho}{2} \left\{ \left\| \boldsymbol{\mathcal{A}} - \boldsymbol{\mathcal{B}}^{(s)} + \rho^{-1} \boldsymbol{\mathcal{W}}_{1}^{(s)} \right\|_{F}^{2} + \left\| \boldsymbol{\mathcal{A}} - \boldsymbol{\Psi}^{(s)} + \rho^{-1} \boldsymbol{\mathcal{W}}_{2}^{(s)} \right\|_{F}^{2} \right\},$$

$$(13)$$

$$\mathcal{B}^{(s+1)} = \arg\min_{\boldsymbol{\nu}, \boldsymbol{B}^{y}, \boldsymbol{B}^{x}, \boldsymbol{B}^{c}} \left\| \left[\boldsymbol{\nu}; \boldsymbol{B}^{y}, \boldsymbol{B}^{x}, \boldsymbol{B}^{c} \right] - \boldsymbol{\mathcal{A}}^{(s+1)} - \rho^{-1} \boldsymbol{\mathcal{W}}_{1}^{(s)} \right\|_{F}^{2} + \left\| \boldsymbol{\Gamma}^{(s)} - \boldsymbol{D}_{p} \boldsymbol{B}^{y} - \rho^{-1} \boldsymbol{W}_{3}^{(s)} \right\|_{F}^{2},$$
(14)

$$\Psi^{(s+1)} = \underset{\Psi}{\operatorname{argmin}} \frac{\rho}{2} \left\| \Psi - \mathcal{A}^{(s+1)} - \rho^{-1} \mathcal{W}_{2}^{(s)} \right\|_{F}^{2} + \tau_{s} \sum_{i,j} \|\psi_{ij}\|_{2}, \tag{15}$$

$$\mathbf{\Gamma}^{(s+1)} = \underset{\mathbf{\Gamma}}{\operatorname{argmin}} \frac{\rho}{2} \left\| \mathbf{\Gamma} - \mathbf{D}_{p} (\mathbf{B}^{y})^{(s+1)} - \rho^{-1} \mathbf{W}_{3}^{(s)} \right\|_{F}^{2} + \sum_{i < i'} f_{\rho} (\| \boldsymbol{\gamma}_{ii'} \|_{2}, \tau_{f}).$$
 (16)

$$\mathcal{W}_{1}^{(s+1)} = \mathcal{W}_{1}^{(s)} + \rho \left\{ \mathcal{A}^{(s+1)} - \mathcal{B}^{(s+1)} \right\},
\mathcal{W}_{2}^{(s+1)} = \mathcal{W}_{2}^{(s)} + \rho \left\{ \mathcal{A}^{(s+1)} - \Psi^{(s+1)} \right\},
\mathcal{W}_{3}^{(s+1)} = \mathcal{W}_{3}^{(s)} + \rho \left\{ \mathcal{D}_{m}(\mathbf{B}^{y})^{(s+1)} - \Gamma^{(s+1)} \right\}.$$
(17)

We then tackle the optimization problems (13) to (16) one-by-one.

The optimization problem in (13) can be split slice-by-slice for $\mathcal{A}[i,\cdot,\cdot]$, $i=1,\ldots,m$. That is, it can be solved with respect to each marginal response process $Y_i(t)$ in a parallel fashion. Define

$$L_i^*(\mu_i, \mathcal{A}[i, \cdot, \cdot]) = \sum_{l=1}^{n_i} \log \left[\phi \left\{ \mu_i + \langle \boldsymbol{G}(t_l^i), \mathcal{A}[i, \cdot, \cdot] \rangle \right\} \right] - \int_0^T \phi \left\{ \mu_i + \langle \boldsymbol{G}(t), \mathcal{A}[i, \cdot, \cdot] \rangle \right\} dt$$

$$+ \frac{\rho}{2} \left\| \mathcal{A}[i, \cdot, \cdot] - \mathcal{B}^{(s)}[i, \cdot, \cdot] + \rho^{-1} \boldsymbol{\mathcal{W}}_1^{(s)}[i, \cdot, \cdot] \right\|_F^2 + \frac{\rho}{2} \left\| \mathcal{A}[i, \cdot, \cdot] - \boldsymbol{\Psi}^{(s)}[i, \cdot, \cdot] + \rho^{-1} \boldsymbol{\mathcal{W}}_2^{(s)}[i, \cdot, \cdot] \right\|_F^2.$$

The objective function $L_i^*(\mu_i, \mathcal{A}[i,\cdot,\cdot])$ is differentiable, and with a large enough ρ , it is almost convex regardless of the form of the link function ϕ . Therefore, we can minimize $L_i^*(\mu_i, \mathcal{A}[i,\cdot,\cdot])$ efficiently using a gradient descent type algorithm. In our implementation, we employ the Newton-Raphson algorithm, as we use the linear and the logit link functions.

The optimization problem in (14) turns to be a regularized CP decomposition with an ℓ_2 penalty. It can be solved by an alternating block updating algorithm (Zhou et al., 2013a), which updates one block of the parameters in $\{B^y, B^x, B^c\}$, while fixing the other two blocks and ν . For instance, $m{B}^y$ is updated by minimizing $\left\|\left\{m{\mathcal{A}}^{(s+1)} +
ho^{-1}m{\mathcal{W}}_1^{(s)}
ight\}_{(1)} - m{B}^y \left[(m{B}^c)^{(s)}\odot(m{B}^x)^{(s)}\operatorname{diag}\left\{m{
u}^{(s)}
ight\}
ight]^\mathsf{T}
ight\|^2$ $+ \left\| \mathbf{\Gamma}^{(s)} -
ho^{-1} \mathbf{W}_3^{(s)} - \mathbf{D}_m \mathbf{B}^y \right\|^2$, with respect to \mathbf{B}^y , where \odot is the Khatri-Rao product, $\mathbf{\mathcal{A}}_{(1)}$ denotes the mode-1 matricization of the tensor \mathcal{A} , and diag(ν) is the diagonal matrix with ν as the diagonal elements. Note that this is essentially a least squares optimization problem with an ℓ_2 penalty, which has an explicit solution. The other two blocks B^x and B^c are updated similarly. After updating each block, for instance, B^y , we update ν_r by normalizing the corresponding vector b_y^y , respectively. In addition, we employ the maximum block improvement strategy of Chen et al. (2012) to ensure the convergence of the alternating block updating iterations (Tang et al., 2019).

The optimization problems in (15) and (16) have explicit solutions, since the corresponding objective functions are convex with respect to ψ_{ij} , and $\gamma_{ii'}$ when $\kappa > \rho^{-1}$, respectively. That is,

$$\psi_{ij}^{(s+1)} = \begin{cases} \mathbf{0} & \text{if } \|\boldsymbol{\vartheta}_{ij}^{(s+1)}\| < \sqrt{K}\tau_s/\rho, \\ \left\{1 - \frac{\sqrt{K}\tau_s/\rho}{\|\boldsymbol{\vartheta}_{ij}^{(s+1)}\|}\right\} \boldsymbol{\vartheta}_{ij}^{(s+1)} & \text{if } \|\boldsymbol{\vartheta}_{ij'}^{(s+1)}\| \ge \sqrt{K}\tau_s/\rho, \end{cases}$$
(18)

$$\psi_{ij}^{(s+1)} = \begin{cases}
0 & \text{if } \|\vartheta_{ij}^{(s+1)}\| < \sqrt{K}\tau_{s}/\rho, \\
\left\{1 - \frac{\sqrt{K}\tau_{s}/\rho}{\|\vartheta_{ij}^{(s+1)}\|}\right\}\vartheta_{ij}^{(s+1)} & \text{if } \|\vartheta_{ij'}^{(s+1)}\| \ge \sqrt{K}\tau_{s}/\rho, \\
\gamma_{ii'}^{(s+1)} = \begin{cases}
\zeta_{ii'}^{(s+1)} & \text{if } \|\zeta_{ii'}^{(s+1)}\| \ge \kappa\tau_{f}, \\
\frac{\kappa\rho}{\kappa\rho-1}\left\{1 - \frac{\tau_{f}/\rho}{\|\zeta_{ii'}^{(s+1)}\|}\right\}_{+} \zeta_{ii'}^{(s+1)} & \text{if } \|\zeta_{ii'}^{(s+1)}\| < \kappa\tau_{f}, \end{cases} (19)$$

where $\boldsymbol{\vartheta}_{ij}^{(s+1)} = \boldsymbol{\mathcal{A}}[i,j,\cdot]^{(s+1)} + \rho^{-1}\{\boldsymbol{\mathcal{W}}_{2}[i,j,\cdot]\}^{(s)}, \ \boldsymbol{\zeta}_{ii'}^{(s+1)} = \left(\boldsymbol{B}^{y}[i,\cdot]\right)^{(s+1)} - \left(\boldsymbol{B}^{y}[i',\cdot]\right)^{(s+1)} + \rho^{-1}\{\boldsymbol{\mathcal{W}}_{2}[i,j,\cdot]\}^{(s)}$ $\rho^{-1}W_3[l_{ii'},\cdot]^{(s)}$, and $l_{ii'}=(2m-i)(i-1)/2+i'-i$. We note that this computation can be done in a parallel fashion over $(i, i'), i, i' = 1, \dots, m$, and $(i, j), i = 1, \dots, m, j = 1, \dots, p$.

We summarize the above optimization procedures in Algorithm 1.

Algorithm 1 The ADMM algorithm for parameter estimation.

```
[1] Initialize \boldsymbol{\mu}^{(0)}, [\boldsymbol{\nu}; \boldsymbol{B}^y, \boldsymbol{B}^x, \boldsymbol{B}^c]^{(0)}, \boldsymbol{\mathcal{A}}^{(0)}, \boldsymbol{\Psi}^{(0)}, \boldsymbol{\Gamma}^{(0)}, \boldsymbol{\mathcal{W}}_1^{(0)}, \boldsymbol{\mathcal{W}}_2^{(0)}, \boldsymbol{\mathcal{W}}_3^{(0)}. Set \rho and \kappa > \rho^{-1}.

```

[2] Update
$$\mu_i^{(s+1)}$$
, $\mathcal{A}[i,\cdot,\cdot]^{(s+1)}$ via (13) with parallel computing over $i=1,\ldots,m$. [3] Update $\left[\!\!\left[\boldsymbol{\nu}^{(s+1)}; \left\{\boldsymbol{B}^y\right\}^{(s+1)}, \left\{\boldsymbol{B}^x\right\}^{(s+1)}, \left\{\boldsymbol{B}^c\right\}^{(s+1)}\right]\!\!\right]$ via (14).

[4] Update
$$\Psi^{(s+1)} = \left\{ \psi_{ij}^{(s+1)} \right\}$$
 via (18) with parallel computing over $1 \le i \le m, 1 \le j \le p$.

[5] Update
$$\Gamma^{(s+1)} = \left\{ \gamma_{ii'}^{(s+1)} \right\}$$
 via (19) with parallel computing over $1 \leq i < i' \leq m$.
[6] Update $\mathcal{W}_1^{(s+1)}, \mathcal{W}_2^{(s+1)}, \mathcal{W}_3^{(s+1)}$ via (17).

until the stopping criterion is met.

Initialization, convergence, tuning, and computational complexity 3.2

We recommend to use a warm initialization, by setting the initial values $\{\mu^{(0)}, \mathcal{B}^{(0)}\}$ as the unpenalized estimators without imposing any low-rank or penalty structures, while setting the other initial values at zeros. We stop the algorithm when some stopping criterion is met, e.g., when the difference of the consecutive estimates is smaller than a threshold.

Algorithm 1 converges to a stationary point. This can be verified by checking the conditions of Proposition 1 in Zhu et al. (2019).

Proposition 2. Suppose the log-likelihood function \mathcal{L} is a Lipschitz function with respect to \mathcal{B} , and the parameter space for B^y , B^x and B^c is a compact set. Then the obtained estimator from Algorithm 1 converges to a stationary point of the objective function in (11).

We select the tuning parameters as follows. The first is the Lagrangian augmented parameter ρ , which can be viewed as the learning rate of the ADMM algorithm. Our numerical results have suggested that the final estimates are not overly sensitive to the choice of ρ , so we simply set $\rho = 1$. The second is the thresholding parameter κ in the fusion penalty f_{κ} . Again, the estimates are not sensitive to κ as long as $\kappa > \rho^{-1}$, and we set $\kappa = 2$. The third set of tuning parameters include the rank R in (8), and the two regularization parameters, τ_s in (9) and τ_f in (10). We tune them by minimizing a Bayesian information criterion (BIC), $-2\mathcal{L}(\boldsymbol{\mu}, \boldsymbol{\mathcal{B}}) + \log(N)p_e$, where $N = \sum_{i=1}^m n_i$ is the total number of events observed on the multivariate response process $\boldsymbol{Y}(t)$, and p_e is the effective number of parameters. For the tuning of R, $p_e = R(m + p + K - 2)$, for τ_s , p_e is the total number of non-zero latent parameters, and for τ_f , p_e is the total number of unique non-zero latent parameters. A similar BIC type criterion has been commonly adopted in low-rank tensor regressions (Zhou et al., 2013a; Sun and Li, 2017). Moreover, to speed up tuning, we tune R, τ_s, τ_f in a sequential manner. That is, we first tune R while setting $\tau_s = \tau_f = 0$, then tune τ_s given the selected R while setting $\tau_f = 0$, and finally tune τ_f given the selected R and τ_s .

Finally, we briefly discuss the computational complexity of Algorithm 1. As an example, if we use a sigmoid link function, then the overall computational complexity can be approximated by $O\left[n_{iter}\left\{mC_{LR(p)}+C_{ALS(mp)}+mp+m(m-1)/2\right\}\right]$, where n_{iter} denotes the total number of ADMM iterations, $C_{LR(p)}$ denotes the computational complexity for a logistic regression with p covariates, and $C_{ALS(mpK)}$ denotes the computational complexity for a three-way tensor decomposition with the size $m \times p \times K$ using the alternating least squares (ALS) algorithm. Besides, several steps in this algorithm can be accelerated using parallel computing. In Section 5, we report the computation time of our simulated examples.

4 Theory

4.1 Regularity conditions

We begin by introducing some notation. Let $\boldsymbol{\theta} = \left\{\boldsymbol{\mu}^\mathsf{T}, \operatorname{vec}(\boldsymbol{B}^y)^\mathsf{T}, \operatorname{vec}(\boldsymbol{B}^x)^\mathsf{T}, \operatorname{vec}(\boldsymbol{B}^c)\right\}^\mathsf{T}$ collect all latent parameters in our model, including the background intensity $\boldsymbol{\mu}$, and the latent factors $\boldsymbol{B}^y, \boldsymbol{B}^x, \boldsymbol{B}^c$ from the CP decomposition (8). Without loss of generality, the normalization weight $\boldsymbol{\nu}$ is omitted to simplify the notation. Let $\boldsymbol{\beta} = \boldsymbol{\beta}(\boldsymbol{\theta}) = \left(\boldsymbol{\beta}_1^\mathsf{T}, \dots, \boldsymbol{\beta}_m^\mathsf{T}\right)^\mathsf{T}$, where $\boldsymbol{\beta}_i = \left\{\mu_i, \operatorname{vec}(\boldsymbol{\mathcal{B}}[i,\cdot,\cdot])^\mathsf{T}\right\}^\mathsf{T}$, $i=1,\dots,m$. Note that the transferring coefficient $\boldsymbol{\beta}$ is a function of $\boldsymbol{\theta}$, and thus we sometimes write it as $\boldsymbol{\beta}(\boldsymbol{\theta})$. Let $\boldsymbol{\Theta}_{\boldsymbol{\theta}} \subset \mathbb{R}^{R(m+p+K)+m}$ and $\boldsymbol{\Theta}_{\boldsymbol{\beta}} \subset \mathbb{R}^{mpK+m}$ denote the parameter space for $\boldsymbol{\theta}$ and $\boldsymbol{\beta}$, respectively. For a real-valued function f(t) defined on $[0,\infty)$, define the norm $\|f\|_A = \left\{\int_A f^2(t)dt\right\}^{1/2}$, where A is a Borel set in $[0,\infty)$. In particular, write $\|f\|_T = \left\{\int_0^T f^2(t)dt\right\}^{1/2}$ for any T>0. Moreover, let $\|\cdot\|_2$, $\|\cdot\|_\infty$, $\|\cdot\|_F$, and $\|\cdot\|_{max}$ denote the ℓ_2 norm, the ℓ_∞ norm, the Frobenius norm, and the maximum norm, respectively. Let $\pi_{min}(\cdot)$ and $\pi_{max}(\cdot)$ denote the smallest and the largest eigenvalue for a symmetric matrix.

For our theoretical analysis, we consider a general likelihood-based loss function, which encompass our model (1) and the two penalty functions (9) and (10),

$$S\{\beta(\boldsymbol{\theta})\} = -\mathcal{L}\{\beta(\boldsymbol{\theta})\} + \tau P\{\beta(\boldsymbol{\theta})\} = -\frac{1}{T} \sum_{i=1}^{m} L_i\{\beta(\boldsymbol{\theta})\} + \tau P(\boldsymbol{\theta}), \tag{20}$$

where $L_i(\cdot)$ is the log-likelihood function for the *i*th response process $Y_i(t)$, while in our model it is as specified in (7), i = 1, ..., m, $P(\cdot)$ is a non-negative penalty function, and τ is the penalization parameter. Note that θ is associated with the log-likelihood function $L_i(\cdot)$ only through $\beta(\theta)$.

We next present a set of regularity conditions, where c_1 to c_5 are some finite positive constants.

- (C1) Let $\mathcal{K}(\boldsymbol{\beta}^0) \subset \boldsymbol{\Theta}_{\boldsymbol{\beta}}$ denote a neighborhood of the true value $\boldsymbol{\beta}^0$. For any $\boldsymbol{\beta}, \tilde{\boldsymbol{\beta}} \in \mathcal{K}(\boldsymbol{\beta}^0)$ and a large enough T, $\lambda_i^y(t;\boldsymbol{\beta}) = \lambda_i^y(t;\tilde{\boldsymbol{\beta}})$ almost surely on [0,T], if and only if $\boldsymbol{\beta} = \tilde{\boldsymbol{\beta}}$.
- (C2) For any $i=1,\ldots,m,\sup_{\mathcal{V}(A)<1}\mathbb{E}\{Y_i(A)\}^2/\mathcal{V}(A)<\infty,$ and for any $j=1,\ldots,p,\sup_{\mathcal{V}(A)<1}\mathbb{E}\{X_j(A)\}^2/\mathcal{V}(A)<\infty,$ where A is a Borel-set on $[0,+\infty)$, and \mathcal{V} is the Lebesgue measure.
- (C3) For any $\boldsymbol{\beta} \in \mathcal{K}(\boldsymbol{\beta}^{0})$, $i = 1, \ldots, m$, $\sup_{t \in [0,T]} \mathbb{E}\left[\left\|\frac{\partial \log\{\lambda_{i}^{y}(t)\}}{\partial \boldsymbol{\beta}_{i}}\lambda_{i}^{y}(t; \boldsymbol{\beta}^{0})\right\|_{\infty}^{2}\right] < \infty$, $\sup_{t \in [0,T]} \mathbb{E}\left[\left\|\frac{\partial^{2} \log\{\lambda_{i}^{y}(t)\}}{\partial \boldsymbol{\beta}_{i}\partial \boldsymbol{\beta}_{i}^{\mathsf{T}}}\lambda_{i}^{y}(t; \boldsymbol{\beta}^{0})\right\|_{max}^{2}\right] < \infty$, and $\sup_{t \in [0,T]} \mathbb{E}\left\{\lambda_{i}^{y}(t)^{2}\right\} < \infty$.
- (C4) For any $\boldsymbol{\beta} \in \mathcal{K}(\boldsymbol{\beta}^0)$, i = 1, ..., m, $\pi_{min}(\boldsymbol{J}_i) \geq c_1$ almost surely with a large T, where $\boldsymbol{J}_i = T^{-1} \int_0^T \boldsymbol{H}_i(t) \boldsymbol{H}_i(t)^\mathsf{T} \lambda_i^y(t, \boldsymbol{\beta}_i^0) dt$, and $\boldsymbol{H}_i(t) = \lambda_i^y(t)^{-1} \partial \lambda_i^y(t) / \partial \boldsymbol{\beta}_i$.
- (C5) The link function $\phi(x)$ is a Lipschitz function satisfying that $|\phi(x_1) \phi(x_2)| \le c_2|x_1 x_2|$ for any $x_1, x_2 \in \mathbb{R}$ and some c_2 .
- (C6) The basis function $g^{(k)}(t)$ satisfies that $\max_{1 \le k \le K} \left\{ \int_0^\infty g^{(k)}(t)^2 dt \right\}^{1/2} < c_3$ for some c_3 .
- (C7) The penalty function $P(\theta)$ is a non-negative Lipschitz function in a neighborhood of the true value θ^0 satisfying that $|P(\theta_1) P(\theta_2)| \le c_4 \|\theta_1 \theta_2\|_2$ for some c_4 .
- (C8) Let $\mathcal{I}_1, \ldots, \mathcal{I}_N$ denote the true subgroup partition of the index set $\{1, \ldots, m\}$, in that $\boldsymbol{B}^y[i, \cdot]$ $= \bar{\boldsymbol{b}}_{(s)}$ for any $i \in \mathcal{I}_s$, $s = 1, \ldots, N$, and N is the number of subgroups. There is a minimum gap, such that $\min_{s \neq s'} \left\| \bar{\boldsymbol{b}}_{(s)} \bar{\boldsymbol{b}}_{(s')} \right\|_2 > c_5$.

We make some remarks about these conditions. Condition (C1) ensures the identifiability of the intensity function with respect to β , and is equivalent to Ogata et al. (1978, Assumption B3). Condition (C2) implies a finite mean intensity for both the response and the predictor process, and the resulting process is referred as a non-explosive point process (Daley and Vere-Jones, 2007). The same condition was imposed in Ogata et al. (1978, Assumption A3) and Hansen et al. (2015, condition of Theorem 2). Such a condition also makes sense in neuronal activity studies, which implies that there is an upper bound for the average neuronal activity level or calcium concentration level over time. Condition (C3) is a standard regularity condition, and the same condition or its equivalent forms have been commonly adopted in the point process literature; see, e.g., Ogata et al. (1978, Conditions B4, B5) for a stationary process, and Rathbun and Cressie (1994, Conditions C1, C4) for an inhomogeneous process. This condition is also easy to verify for a class of commonly used link functions, e.g., a rectifier link or a sigmoid link. Condition (C4) is placed on the minimum

eigenvalue of the information matrix. A similar condition was considered in Ogata et al. (1978, Assumption B6) and Rathbun and Cressie (1994, Condition c), and it is analogous to the usual regularity condition placed on the design matrix for regressions with random variables. Condition (C5) is usually adopted in nonlinear point process models (Brémaud and Massoulié, 1996), and it holds for a range of commonly used link functions. Similarly, Condition (C6) holds for numerous basis functions, since the basis function is generally a normalized decaying kernel. Condition (C7) holds for a variety of penalty functions in a compact space, including the ℓ_1 and ℓ_2 penalties, the group ℓ_1 penalty in (9), and the fusion penalty in (10). Finally, Condition (C8) is a standard condition to ensure the identifiability of the subgroups, and has been often assumed in subgroup analysis (Ma and Huang, 2017; Zhu et al., 2019). This condition is not required for establishing the coefficient estimation convergence properties, but only for the subgroup identification consistency. In summary, we feel the above regularity conditions are relatively mild and reasonable. They are clearly weaker than the stationary condition. The same conditions or similar forms have been widely adopted in the asymptotic studies of temporal point process in the literature.

4.2 Convergence properties

We next derive the asymptotic properties for the penalized likelihood estimator from (20), which covers a variety of link and penalty functions, and does not assume the stationarity. We allow the point process dimension to diverge, and show that the increasing dimension is to actually benefit the estimation, leading to a faster convergence rate for the coefficient estimator and a smaller error bound for the recovered intensity function. In the interest of space, we present some supporting lemmas and the proofs in the Supplementary Appendix.

Since the parameter spaces Θ_{θ} and Θ_{β} grow along with the point process dimensions, we adopt the sieve idea and the large-deviation approach introduced by Shen and Wong (1994); Shen (1998) to derive the asymptotics. Specifically, we define a restricted parameter space for θ ,

$$\tilde{\mathbf{\Theta}}_{\boldsymbol{\theta}} = \left\{ \boldsymbol{\theta} \in \mathbf{\Theta}_{\boldsymbol{\theta}} : \|\boldsymbol{\theta}\|_{\infty} \le c_0, P(\boldsymbol{\theta}) \le c_{\boldsymbol{\theta}}^2 \right\},$$

where c_0 is a positive constant, and c_{θ} is another constant that is allowed to increase at the rate of $O\left(\sqrt{(m+p+K)R+m}\right)$, since the dimension of θ is (m+p+K)R+m that is to diverge with m and p. Furthermore, we define a metric based on the Kullback-Leibler (KL) pseudo-distance in Θ_{θ} with respect to the underlying true value θ^0 as,

$$d(\boldsymbol{\theta}, \boldsymbol{\theta}^0) = \frac{1}{\sqrt{mp}} \mathbb{E} \left[\mathcal{L} \{ \boldsymbol{\beta}(\boldsymbol{\theta}) \} - \mathcal{L} \{ \boldsymbol{\beta}(\boldsymbol{\theta}^0) \} \right]^{1/2}.$$

Analogous to Ogata et al. (1978, Lemma 3), it is straightforward to verify that $d(\theta, \theta^0)$ is an appropriate distance metric for any $\theta \in \Theta_{\theta}$. Let $\hat{\theta} = \operatorname{argmin}_{\theta \in \tilde{\Theta}_{\theta}} \mathcal{S}\{\beta(\theta)\}$ denote the penalized likelihood estimator for (20). The next theorem shows that $\hat{\theta}$ converges to the true value θ^0 exponentially in probability under the KL distance.

Theorem 1. Suppose Conditions (C1) to (C7) hold. For some $\varepsilon_1 > 0$, there exist finite positive constants \tilde{c}_1, \tilde{c}_2 , such that

$$Pr\left\{d(\hat{\boldsymbol{\theta}}, \boldsymbol{\theta}^0) \ge \varepsilon_1\right\} \le 7 \exp\left(-\tilde{c}_2 T \eta_{\boldsymbol{\theta}}^2 \varepsilon_1^2\right),$$

where

$$\eta_{\theta} = \frac{(mpK)^{1/2}}{\{R(m+p+K)+m\}^{1/2}} \left[\log \left\{ \frac{\tilde{c}_1 mpK}{\sqrt{R(m+p+K)+m}} \right\} \right]^{-1/2},$$

and the penalty parameter τ in (20) satisfies that $\tau \leq O(T^{-1}\eta_{\theta}^{-2})$.

The convergence result in Theorem 1 is established under the KL distance, which is stronger than and usually dominates some other distance measures, e.g., the Hellinger metric. The next corollary establishes the convergence of the recovered transferring coefficient \mathcal{B} under the ℓ_2 norm. Denote $\hat{\mathcal{B}} = \mathcal{B}(\hat{\theta})$, $\mathcal{B}^0 = \mathcal{B}(\theta^0)$, and $\tilde{d}(\hat{\mathcal{B}}, \mathcal{B}^0) = (mpK)^{-1/2} ||\hat{\mathcal{B}} - \mathcal{B}^0||_F$.

Corollary 1. Suppose the conditions in Theorem 1 hold. For some $\varepsilon_2 > 0$, there exists a finite positive constant \tilde{c}_3 , such that

$$Pr\left\{\tilde{d}(\hat{\mathcal{B}},\mathcal{B}^0) \ge \varepsilon_2\right\} \le 7 \exp\left(-\tilde{c}_3 T \eta_{\mathcal{B}}^2 \varepsilon_2^2\right),$$

where $\eta_{\mathcal{B}} = [(mpK)/\{R(m+p+K)+m\}]^{1/2}$.

A few remarks are in order. First, Theorem 1 and Corollary 1 indicate that the penalized estimator and the recovered coefficient tensor achieve a convergence rate of $\sqrt{T}\eta_{\theta}$ and $\sqrt{T}\eta_{\mathcal{B}}$, respectively. On one hand, since the length T of the observed point process plays the role of sample size as in the usual random variable based regressions, an increasing T would lead to a faster convergence rate and a smaller error bound. On the other hand, the diverging point process dimension m and p are to benefit the estimation as well. This is achieved not because of a stronger set of model and regularity conditions we impose; actually as we discuss in detail earlier that our conditions are compatible with or weaker than those in the existing literature. But it is indeed due to our proposed low-rank model structure (8). Specifically, our model substantially reduces the size of the parameter space Θ_{β} through $\mathcal{B}(\theta)$ with the latent parameter $\theta \in \Theta_{\theta}$. Consequently, it enables us

to obtain a smaller metric entropy with bracketing on the restricted parameter space $\tilde{\Theta}_{\theta}$, which in turn yields a tighter bound for the loss function and a faster convergence rate. Moreover, the latent factors B^x and B^c are commonly shared across the intensity functions of all response processes. This enables us to utilize and borrow information from the entire multivariate response process Y(t) rather than a single response $Y_i(t)$. This result of the blessing of dimensionality clearly distinguishes our method from the existing ones; e.g., Bacry et al. (2020) studied the asymptotics for a multivariate Hawkes process model and potentially allowed the process dimension to diverge, but their error bound is to increase at the rate of the logarithm of the dimension when it diverges. Second, in our current analysis, we fix the rank R of the tensor decomposition (8) for simplicity. However, we can allow R to diverge along with m and p too. By Corollary 1, as long as R grows at a limited rate of $o(\min(m, p))$, e.g., $\log(m)$ or $\log(p)$, the obtained estimator still enjoys a faster convergence rate as m and p increase. Third, we note that the theoretical properties obtained in Theorem 1 and Corollary 1 are for the global minimizer of (20). Nevertheless, (20) is a non-convex optimization problem, and there is no guarantee that the optimization algorithm can land at the global minimizer. This is a well-known issue in almost any statistical models involving non-convex optimization (Zhu et al., 2016), and it still remains an open question. In recent years, there has been some progress to tackle this problem. For instance, Bi et al. (2018) showed that, in a tensor factorization model, the established large deviation property of a global minimizer can be generalized to an asymptotically good local optimizer. However, it was obtained with the price of imposing additional assumptions. We leave this problem as future research.

Finally, we establish the subgroup structure identification consistency based on the estimated transferring coefficients.

Theorem 2. Suppose Conditions (C1) to (C8) hold. Let $\hat{\mathbf{B}}^y$ denote the estimated latent factor \mathbf{B}^y from (11). Suppose $\tau_s = o\left\{ \left(T\eta_{\mathbf{B}}^2\right)^{-1/2} \right\}$, and $\tau_f = O\left\{ \left(T\eta_{\mathbf{B}}^2\right)^{-1/2+c_f} \right\}$ for $0 < c_f < 1/2$. Then, $Pr\left(\hat{\mathbf{B}}^y[i,\cdot] = \hat{\mathbf{B}}^y[i',\cdot] \mid i,i' \in \mathcal{I}_s, \ 1 \le s \le N \right) \to 1$, as $T \to \infty$.

Theorem 2 shows that, as $T \to \infty$, the true subgroup structure can be identified with the probability tending to one. We also comment that, the number of subgroups is also allowed to increase as m increases, as long as Condition (C8) holds. Moreover, we may relax (C8), by allowing the minimum gap c_5 to decrease at a limited rate. For instance, Theorem 2 continues to holds if $c_5 \to 0$ and $c_5 T^{1/2-c_f} \to \infty$. Finally, we comment that, the imposed subgrouping structure encourages grouping of similar response processes, which helps further integrate the information across different individual processes.

5 Simulations

5.1 Model with low-rank and sparsity structures

We study the finite-sample performance of the proposed method under different predictor processes, link functions ϕ , point process dimensions m,p and time length T. We first consider a model with the low-rank and sparsity structure in this section, then a model with an additional subgroup structure in the next section.

We generate the data following model (6). Specifically, we first generate the p-dimensional predictor point process X(t). We consider two predictor processes, a homogeneous Poisson process with the marginal intensity Λ_i^x , and a Hawkes process with the transferring function $\omega_{jj'}(t)=a_{jj'}e^{-\beta t}$ and the initial intensity $\Lambda_j^{(0)}$, where $\alpha_{jj'}$ is generated from a uniform distribution on [0.2, 0.3], $\beta = 0.7$, and $j, j' = 1, \dots, p$. We consider two intensity link functions ϕ , a linear link and a logit link. For the linear link, we set the marginal intensity $\Lambda_i^x = 0.5$ for the Poisson predictor process, and set the initial intensity $\Lambda_j^{(0)}=0.3$ for the Hawkes predictor process, $j=1,\ldots,p$. For the logit link, we set $\Lambda^x_j=0.2$ for the Poisson process, and set $\Lambda^{(0)}_j=0.15$ for the Hawkes process, $j=1,\ldots,p$. This way, the Poisson and Hawkes predictor processes are generated with similar levels of overall intensities. Next, we employ a mixture of three basis functions, $g^{(1)}(t) = \exp(-5t)$, $g^{(2)}(t) = 0.2 \, \mathbf{1}(t \le 0.1)$, and $g^{(3)}(t) = 0.05 \, \mathbf{1}(t \le 1)$. The first basis function is an exponential decaying kernel that is widely used in point process modeling. The other two basis functions are piecewise indicator functions, and they are used to capture some "short-term" effect and "longterm" effect, respectively, that are motivated by neuronal spike trains analysis. Next, we generate the transferring coefficient tensor ${\cal B}$ with a rank-3 structure, ${\cal B}=\sum_{r=1}^3 \nu_r {m b}_r^y \circ {m b}_r^x \circ {m b}_r^c$. For the linear link, we set $\nu = (0.3, 0.2, 0.3)^{\mathsf{T}}$,

and \boldsymbol{b}_r^c , $\boldsymbol{\eta}_r^y$ and $\boldsymbol{\eta}_r^x$, r=1,2,3, are all generated from a normal distribution with mean one and covariance the identity matrix. Figure 1(a) shows the true association structure based on the generated coefficient $\boldsymbol{\mathcal{B}}$. For the logit link, we set $\boldsymbol{\nu}=(0.2,0.1,0.2)^{\mathsf{T}}$, and generate $\boldsymbol{b}_r^y,\boldsymbol{b}_r^x,\boldsymbol{b}_r^c$ in the same way as for the linear link, except that we add a negative sign to each element of $\boldsymbol{\mathcal{B}}$ with probability 0.5. Finally, we set the background intensity $\boldsymbol{\mu}=\mathbf{0.01}_m$, then generate the m-dimensional response point process $\boldsymbol{Y}(t)$ following model (6). Given the intensity function, each individual re-

- (b) True model coefficients in Section 5.2

Figure 1: The slice of the true transferring coefficient tensor \mathcal{B} , where each entry is $\|\beta_{ij}\|_2$.

sponse process is simulated following the thinning strategy (Ogata, 1988). We set the dimension of the response and predictor process $m=p=\{60,120\}$, and the observed length $T=\{800,2000\}$. For a homogeneous process, T plays the role of sample size, since it is proportional to the expected number of events. For an inhomogeneous process, this is not necessarily true, and the expected number of observed events could vary across different marginal processes.

We compare our method with two alternative solutions. The first is a standard baseline model that simply fits the conditional intensity functions in (1) without specifying any additional structure. The second adds a group ℓ_1 penalty on the transferring coefficients to the baseline model for sparsity-pursuit, which is analogous to Hansen et al. (2015). We evaluate the estimation accuracy by the root mean square error (RMSE) of the estimated coefficient tensor \mathcal{B} .

Table 1 summarizes the results based on 50 data replications. It is seen that our proposed method consistently outperforms the two alternative solutions, as it achieves the smallest RMSE across all settings. As the point process length T increases, all methods improve in estimation accuracy. On the other hand, as the numbers of point processes m and p increase, our method continues to improve, whereas the two alternative solutions suffer. This is largely due to that our method jointly model all the point processes together, instead of one at a time. Figure 2 shows the recovered transferring structure based on the estimated \mathcal{B} with a linear link and a Poisson predictor process. It is seen again that our method is capable of recovering the transferring structure successfully, while the other two methods cannot.

5.2 Model with additional subgrouping structure

We next consider a model with an additional subgrouping structure. For simplicity, we focus on the linear link ϕ and the Poisson predictor process. The results are similar for other combinations of

Table 1: Estimation accuracy of the transferring coefficient tensor \mathcal{B} for the model in Section 5.1. Three methods are compared: the regular point process regression model (PP-Reg), the sparse point process regression with a group ℓ_1 penalty (SpPP-Reg), and our proposed method. Reported are the average RMSE based on 50 replications, with the standard errors in the parenthesis.

link function and predictor process. We adopt the same simulation setup as in Section 5.1, except that we generate the transferring coefficient tensor $\boldsymbol{\mathcal{B}}$ in a different way. Specifically, we consider a rank-4 structure $\boldsymbol{\mathcal{B}} = \sum_{r=1}^4 \nu_r \boldsymbol{b}_r^y \circ \boldsymbol{b}_r^x \circ \boldsymbol{b}_r^c$. We set $\boldsymbol{\nu} = (0.2, 0.2, 0.2, 0.2)^\mathsf{T}$,

$$\begin{aligned} & \boldsymbol{b}_{1}^{y} = \left((\eta_{1}^{y} \mathbf{1})_{p/6}^{\mathsf{T}}, \mathbf{0}_{5p/6}^{\mathsf{T}} \right)^{\mathsf{T}}, & \boldsymbol{b}_{1}^{x} = (\boldsymbol{\eta}_{1}^{x})_{m}, \\ & \boldsymbol{b}_{2}^{y} = \left(\mathbf{0}_{p/6}^{\mathsf{T}}, (\eta_{2}^{y} \mathbf{1})_{p/6}^{\mathsf{T}}, \mathbf{0}_{2p/3}^{\mathsf{T}} \right)^{\mathsf{T}}, & \boldsymbol{b}_{2}^{x} = \left((\boldsymbol{\eta}_{2}^{x})_{m/2}^{\mathsf{T}}, \mathbf{0}_{m/2}^{\mathsf{T}} \right)^{\mathsf{T}}, \\ & \boldsymbol{b}_{3}^{y} = \left(\mathbf{0}_{p/3}^{\mathsf{T}}, (\eta_{3}^{y} \mathbf{1})_{p/3}^{\mathsf{T}}, \mathbf{0}_{p/3}^{\mathsf{T}} \right)^{\mathsf{T}}, & \boldsymbol{b}_{3}^{x} = \left(\mathbf{0}_{m/3}^{\mathsf{T}}, (\boldsymbol{\eta}_{3}^{x})_{m/3}^{\mathsf{T}}, \mathbf{0}_{m/3}^{\mathsf{T}} \right)^{\mathsf{T}}, \\ & \boldsymbol{b}_{4}^{y} = \left(\mathbf{0}_{2p/3}^{\mathsf{T}}, (\eta_{4}^{y} \mathbf{1})_{p/3}^{\mathsf{T}} \right)^{\mathsf{T}}, & \boldsymbol{b}_{4}^{x} = \left(\mathbf{0}_{2m/3}^{\mathsf{T}}, (\boldsymbol{\eta}_{4}^{x})_{m/3}^{\mathsf{T}} \right)^{\mathsf{T}}, \end{aligned}$$

 b_r^c , η_r^x are all generated from a normal distribution with mean one and the identity covariance, and η_r^y , r=1,2,3,4, are generated from a univariate normal distribution with mean one and variance 0.1. Note that, unlike the coefficient tensor in Section 5.1, here the entries are repeated in b_r^y , which in turn induces the subgrouping structure. This structure can also be seen in Figure 1(b), which shows a slice of one generated coefficient tensor \mathcal{B} . We set the dimension of the response and predictor process $m=p=\{60,120\}$, and the observed length $T=\{1200,2400\}$.

Table 2 summarizes RMSE based on 50 data replications, and Figure 3 shows recovered transferring structure. It is again seen that our proposed method consistently outperforms the two alter-

Figure 2: Recovered transferring coefficient tensor \mathcal{B} for the model in Section 5.1. Three methods are compared: the regular point process regression model (PP-Reg), the sparse point process regression with a group ℓ_1 penalty (SpPP-Reg), and our proposed method.

native solutions in terms of estimation accuracy. Moreover, Table 2 includes the rand index statistic for our proposed method, which evaluates the clustering performance. It is seen that our method achieves a high index value in all settings.

As for the computation time, for the simulation example in Section 5.1 with a linear link, a Poisson predictor process, m=p=60 and T=2000, the average computing time was about 1.1 minutes. For the example in Section 5.2 with m=p=60 and T=2400, the average computing time was about 1.9 minutes. All computations were done on a personal laptop with Intel(R) Core(TM) i7-8565U CPU@1.8GHz.

Table 2: Estimation and clustering accuracy of the transferring coefficient tensor \mathcal{B} for the model in Section 5.2. Three methods are compared: the regular point process regression model (PP-Reg), the sparse point process regression with a group ℓ_1 penalty (SpPP-Reg), and our proposed method. Reported are the average RMSE based on 50 replications, with the standard errors in the parenthesis. Rand index for our method is also reported.

6 Cross-area Neuronal Spike Trains Analysis

Ensemble neural activity analysis is of central importance in system neuroscience, which aims to understand sensory coding and associations with motor output and cognitive functions (Brown et al., 2004; Kim et al., 2011). Some goals of common interest include the study of single-neuron activity with dependence on its own history, and the study of cross-neuron correlations based on spike trains similarities within the same area. Beyond those goals, it is also of key interest to understand the communication patterns in information transmission between neurons in different brain areas through neuronal spiking activities (Saalmann et al., 2012). A group of neurons could be identified within a brain area based on their similar exciting or inhibitory effects onto another group of neurons in a different brain area. This hypothesis has been suggested by several scientific studies. For instance, Liang et al. (2013) found that there might be discrete locations within the visual cortex area that respond to specific cross-modal inputs such as auditory or tactile. That is, the neurons in the V1 area are expected to be clustered in that they share similar cross-cortexarea association patterns, which needs to be inferred from the associations between the observed spike trains activities. In addition, the signal transmission takes time from one area to another, suggesting that the cross-area neuronal connection may account for a time-dependent convolutional effect rather than a simple co-firing. In recent years, benefitting from the rapid development of imaging techniques such as the calcium imaging, we are now able to monitor a large number of neurons simultaneously with a single-neuron resolution in a short time period, which produces high-dimensional point process type data of neuronal spike trains.

In our study, we simultaneously measure the neuronal spike trains activities of 139 neurons and 283 neurons from two sensory cortical areas, A1 and V1, in a rat brain, respectively. We collect the data over 192 seconds under a stable stimulus. With 50 millisecond as a unit of time, we obtain

Figure 3: Recovered transferring coefficient tensor \mathcal{B} for the model in Section 5.2. Three methods are compared: the regular point process regression model (PP-Reg), the sparse point process regression with a group ℓ_1 penalty (SpPP-Reg), and our proposed method.

the length of time interval of [0, 3840]. Figure 4 shows the recorded neuron firing events over time, and the histogram summary of the numbers of observed firings for individual neurons in each of these two areas. It is seen that most neurons have their numbers of observed firing events under 200, whereas a subset of neurons have the numbers below 100.

Since a primary goal is to understand the information transmission from the A1 area to the V1 area, we fit the data using our proposed multivariate temporal point process regression, by treating the neuronal spike trains in V1 as the response point process, and the neuronal spike trains in A1 as the predictor process. Since the observed firing events are sparse, we choose a logit link function.

Figure 4: The neuron firings in the V1 and A1 areas. The heatmaps (upper panels) show the neuron-wise firings over time. The histograms (lower panels) summarize the number of firings for each neuron.

We select three basis functions, similarly as in our simulation studies: $g^{(1)}(t) = \exp(-t)$, $g^{(2)}(t) = 0.21(t \le 1)$, and $g^{(3)}(t) = 0.051\{t \le 5\}$, with the time intervals in the indicator functions selected based on the existing scientific findings that the communication process between ensemble neurons across areas mostly happens within tens of milliseconds (Luo et al., 2016). In addition to our proposed model, we also fit the marginal model that takes one response process at a time. Since some neurons have very limited number of firing events, the corresponding model fittings may not converge. Actually, for our data, we have found that about one third of the individual response process fittings cannot converge. To handle this convergence issue, we add an ℓ_2 regularization to this marginal approach, though we still refer to it as a marginal method. Moreover, we fit the marginal model with a group ℓ_1 regularization, similarly as in our simulations.

To evaluate the model, we split the point processes into a training set, i.e., the spike trains data in the time interval [0, 2000), and a testing set, i.e., the data in the time interval (2000, 3800]. We report two evaluation criteria. The first criterion is the area under the ROC curve (AUC) based on

Table 3: Evaluation of the model fitting for the cross-area neuronal spike trains analysis. Three methods are compared: the regular point process regression model (PP-Reg), the sparse point process regression with a group ℓ_1 penalty (SpPP-Reg), and our proposed method.

	PP-Reg	SpPP-Reg	Our method
Deviance	0.388	0.256	0.185
AUC	0.537	0.579	0.682

a binary prediction (Luo et al., 2016). That is, we bin the continuous point process into a sequence of binary values based on a unit of time of 50 milliseconds, with one meaning that there is a firing event in this time bin, and zero otherwise. We then produce a sequence of binary predictions based on the predicted intensity function for the testing data. The second criterion is the deviance $\|\hat{\boldsymbol{\mathcal{B}}}_{training} - \hat{\boldsymbol{\mathcal{B}}}_{testing}\|$. That is, we obtain the estimated coefficient tensor $\boldsymbol{\mathcal{B}}$ from the training data and testing data, respectively, and evaluate the difference between the two in the Frobenius norm. Intuitively, if the firing patterns have been consistent, then this deviance measure should be small. Table 3 reports the results. It is seen that our proposed method achieves the highest AUC value and the lowest deviance value, suggesting a competitive performance of the proposed method compared to the two alternative solutions. We also identify five subgroups of neurons with our method, which requires future scientific validation, as we do not have relevant subgroup information for this dataset.
